A Modal Deconstruction of Löb Induction

DANIEL GRATZER, Aarhus University, Denmark

We present a novel analysis of the fundamental Löb induction principle from guarded recursion. Taking advantage of recent work in modal type theory and univalent foundations, we derive Löb induction from a simpler and more conceptual set of primitives. We then capitalize on these insights to present Gatsby, the first guarded type theory capturing the rich modal structure of the topos of trees alongside Löb induction without immediately precluding canonicity or normalization. We show that Gatsby can recover many prior approaches to guarded recursion and use its additional power to improve on prior examples. We crucially rely on homotopical insights and Gatsby constitutes a new application of univalent foundations to the theory of programming languages.

CCS Concepts: • **Theory of computation** → **Type theory**; **Modal and temporal logics**; **Categorical semantics**.

Additional Key Words and Phrases: Guarded recursion, modal type theory, homotopy type theory, cubical type theory

1 Introduction

Recursive definitions have long been both a hallmark of the theory of programming languages and a sore point for type theory. Topics as varied as the denotational semantics of λ-calculus or logical relations for higher-order mutable references all prominently feature complex recursive definitions at their heart. Those techniques which construct solutions for such recursive equations (domain theory, step-indexing, etc.) are among the most used within programming language theory.

On the other hand, recursive definitions in type theory introduce two serious complications. First, and most notably, they are simply unsound in general. A type theory that includes an unrestricted fixed-point operator is easily seen to be unsound with $\mathrm{fix}(x.x) : \bot$. This problem is usually addressed by restricting the fixed-point operator to apply only to types and operations where we can guarantee the existence of a fixed-point. A typical such example is present in proof assistants like Coq or Agda, where only structural recursion is permitted. This discipline is sufficient to accommodate inductive arguments and similar, but insufficient for the equations arising in programming languages which often fail to even induce a monotone operator. A successful line of work (*guarded domain theory*) has focused on replacing recursive equations with *guarded* recursive equations and applying the results to programming languages [2, 8, 9, 36].

1.1 Guarded Type Theory

Guarded domain theory extends type theory with a new connective ▶ (pronounced *later*) where intuitively ▶A classifies computations which will eventually produce an element of A but only after work has been done. Crucially, while there is a natural map $\mathsf{next} : A \to \blacktriangleright A$ there is no natural map in the reverse direction. It is therefore sound to add a restricted version of fix, Löb induction:

$$\mathsf{loeb} : (\blacktriangleright A \to A) \to A$$

Even after making such a restriction, however, a second problem emerges: decidability. Modern type theories strive to maintain a decidable type-checking in order to facilitate an implementation and even adding the more restrictive operator loeb with the computation rule $\mathsf{loeb}(f) = f(\mathsf{next}(\mathsf{loeb}(f)))$ is sufficient to render type-checking undecidable. This problem, along with other complications with integrating ▶ into dependent type theory, has motivated over a decade of proposals for guarded type theory.

Thesis 1. *We can summarize the aspirations for an ideal guarded type theory as the following goals:*

(1) *Include* ▶ *along with e.g., the* always *comonad* □ *such that* □▶$A \simeq A$
(2) *Include* loeb *with a propositional equality stating it unfolds.*
(3) *Ensure that closed elements of* **Nat** *compute to numerals.*
(4) *Ensure that type-checking is decidable.*[1]

Example 1.1. In Goal 1, we note that most uses of guarded recursion require additional modalities in order to express computations which neither produce a value this step (A) or a value "one step later" (▶A). For instance, □A signifies a computation which produces all information available from A immediately and without requiring any additional steps. For this reason, □▶A is equivalent to □A; producing all information at once ensures that the delay caused by the ▶ is irrelevant. Many other modalities have been proposed for modeling guarded recursive computations [3, 23].

Example 1.2. We illustrate how these requirements may be used simultaneously. We use 1 and 2 to define the type of guarded streams alongside a propositional equality $\mathsf{GStr} = \mathbf{Nat} \times \blacktriangleright\mathsf{GStr}$. Using 2 again, we then construct e.g., fibs the guarded stream of Fibonacci numbers. This step is a key advantage of guarded *dependent* type theory—term-level guarded recursion can be used to produce guarded recursive types through universes [7]. With the always comonad from 1, we can pass under n copies of ▶ to extract the nth element of fibs. Finally, 3 ensures that this natural number computes to a genuine numeral while 4 implies that the entire program could be implemented in a proof assistant.

Despite the considerable effort expended on guarded recursion, no guarded type theory is known to satisfy Thesis 1, though recent work on $\mathsf{CloTT}_{\square}$ [25] satisfies Goals 1 and 2 and conditionally satisfies Goals 3 and 4. In this paper, we contribute a new approach to Goal 2 and use this insight to construct a new type theory which certainly satisfies Goals 1 and 2 and which we conjecture satisfies all four of these requirements.

Historically, even the first of these goals was a serious challenge since the integration of multiple interacting modalities proved to be difficult. For instance, much of the work on guarded recursion uses the global sections or *always* comonad □, which cannot be included as an operation $\mathbf{U} \to \mathbf{U}$ in type theory [40]. Early attempts to incorporate both ▶ and □ simultaneously precluded the final two desiderata without even considering Löb induction [12, 15].

Recently, Gratzer et al. [21] proposed MTT as a convenient framework for dependent type theories supporting arbitrarily many modalities, including all those necessary for guarded recursion. Later

[1] This requirement is tantamount to requiring a normalization algorithm.

work [18] has further shown that MTT enjoys both decidable type-checking and canonicity, ensuring that this general framework can be instantiated to automatically yield a type theory satisfying Goals 1, 3 and 4. Unfortunately, balancing these requirements with Goal 2 has proven to be another substantial challenge.

Two flavors of MTT have been proposed which include Löb induction [20, 21]. Both involve adding loeb as an axiom but thereafter diverge: either adding an axiom ensuring that it unfolds up to propositional equality or simply adding a definitional equality to this effect. Adding only propositional unfolding will preclude validating Goal 3 in the resulting type theory. Gratzer and Birkedal [20] showed, however, that adding definitional unfolding will address Goal 3 at the cost of refuting Goal 4. Indeed, the "no-go" theorem of op. cit. caused type theorists to weaken the second aspiration of guarded type theory from "include loeb with a definitional unfolding equation" to the 2 we listed above.

In this work, we deviate from both of these approaches. We do not start by axiomatizing Löb induction and attempting to balance its computation rule with decidability. Instead, we enrich our modal framework to obtain **Gatsby** and *derive* Löb induction from these more basic principles.

1.2 Guarded Accessible Type Theory: Gatsby

Following prior work, we also build Gatsby atop MTT. To do so, we must choose a mode theory—a small 2-category—specifying the collection of modalities we wish to use. Roughly, each object m represents a different type theory which are connected by a modality $\langle \mu \mid - \rangle$ (itself something like a functor) for each morphism μ in $\mathcal{M}$. Finally, the 2-cells in a mode theory introduce transformations between modalities. However, instantiating MTT on its own is insufficient. We prove that it is impossible to derive Löb induction just from modalities:

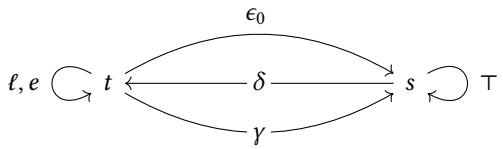
Theorem 2.6 (No-go)**.** *For any $\mathcal{M}$ and $\mu \in \mathcal{M}$, there is no term $(\langle \mu \mid \mathbf{Void} \rangle \to \mathbf{Void}) \to \mathbf{Void}$ in cubical MTT instantiated with $\mathcal{M}$.*

This is because nothing in MTT prevents modalities from being trivial: there is always a model of the system which realizes each modality by the identity. To rule out such degenerate models, we then isolate a simple reasoning principle, similar to existing rules in cubical type theory, which enriches the entire system enough to rule out trivial models and thereby derive Löb induction.

1.2.1 From Modalities to Löb Induction. While no mode theory is sufficient on its own, we must first choose a particular mode theory with which to instantiate MTT. In our case, we have two modes t and s. The first t represents the guarded type theory and will intuitively model the topos of **t**rees $\mathbf{PSh}(\omega)$. The second s is meant to represent ordinary non-guarded type theory and will attempt to model **s**ets. These modes are then linked by a collection of modalities, and the modalities are equipped with a partial order. We give the entire mode theory in Fig. 1. Many aspects of this mode theory were already explored by Gratzer et al. [21]. For instance, ℓ and e correspond to $\blacktriangleright$ and its left adjoint $\blacktriangleleft$. The composites $\delta \circ \epsilon_0$ and $\delta \circ \gamma$ correspond to the possibly and always modalities $\Diamond$ and $\Box$, though we have chosen to break them into adjunctions.

The crucial novelty to our system is in the final modality: $\top$. Ironically, this modality represents the simplest possible modality, the one which sends every type to **Unit**. However, while Theorem 2.6 shows that it is impossible to realize loeb just from modalities, if we force $\langle \top \mid A \rangle \simeq \mathbf{Unit}$, this impacts the behavior of the other modalities enough to make loeb induction derivable.

Concretely, we isolate a particular proposition acc at mode t and show that under the assumption of acc both Löb induction and its unfolding principle are derivable. While this proposition is true in our intended model, it is not derivable in Gatsby. Indeed, the aforementioned result of Gratzer and Birkedal [20] shows that it must not be if Gatsby is to enjoy decidable type-checking. However,



$$\mathsf{id} \le \ell \qquad \mathsf{id} \le \ell \circ e \qquad e \circ \ell = \mathsf{id} \qquad \gamma \circ \delta = \mathsf{id} \qquad \gamma \circ \ell = \gamma \circ e = \gamma \qquad \delta \circ \gamma \le \mathsf{id}$$

$$\epsilon_0 \circ \delta = \mathsf{id} \qquad \mathsf{id} \le \delta \circ \epsilon_0 \qquad \xi \le \nu \circ \top \circ \mu \qquad \top \circ \epsilon_0 = \epsilon_0 \circ \ell$$

Fig. 1. $\mathcal{M}_{\text{Gatsby}}$: the mode theory for Gatsby

this is where the more sophisticated modal framework and special behavior of $\top$ comes into play. While acc is not provable, $\langle \mu \mid \mathsf{acc} \rangle$ holds for a large class of modalities μ.

One can then write a program which assumes acc and thereby has access to Löb induction and guarded reasoning. Once the program is completed, a user can apply $\langle \mu \mid - \rangle$ to the entire closed term and discharge the acc assumption to actually compute a result. In this manner, the choice of μ plays the role of type-based "fuel", allowing a user to extract arbitrary but finite prefixes from a guarded type without requiring the type-checker to compare infinite types.

1.2.2 Working with Accessible Types. While theoretically sufficient, the prospect of carrying acc through every computation is unpleasant. Moreover, in a theory like Gatsby with modalities, real problems could possibly emerge. For instance, we may pass under $\Box$ and lose access to the acc assumption we desired. Both problems can be resolved simultaneously by restricting to types which are *accessible*, i.e., where A is equivalent to $\mathsf{acc} \to A$. Intuitively, these are types for which there is a canonical and best way to discharge an acc assumption and so it can be done automatically.

When working with an accessible type, there is no need to carry around a proof of acc as it can always be obtained from the goal itself. We show that that the subuniverse of accessible types supports a model of guarded type theory closed under all the connectives of type theory, including all modal operators and the universe. Remarkably, even types like booleans, natural numbers, and $\Box A$ are automatically accessible. The result is that essentially any standard guarded recursive algorithm will need to mention only accessible types, freeing the user from any obligation to think about acc when programming. Formally, we have the following result:

Theorem 3.13 (Completeness)**.** *Any program written in MLTT with* $\blacktriangleright$, $\Box$, *and* loeb *with propositional unfolding can be compositionally encoded in Gatsby such that the standard connectives of MLTT except universes are realized by precisely the same operations in Gatsby.*

Informally, our strategy is complete with respect to the standard formulation of guarded recursion.

1.3 Closely Related Approaches

While comparison to related work is carried out in Section 7, two approaches are sufficiently close to warrant earlier mention: stratified guarded type theory [20] and clocked cubical type theory [4, 25].

Stratified guarded type theory (GuTT) [20] balances the tensions of Thesis 1 by proposing two separate but related type theories: one satisfying Goals 1, 2 and 4 and one satisfying Goals 1 to 3. Gatsby sharpens this idea by careful unifying these theories through a more sophisticated modal analysis of Löb induction. In particular, by discarding GuTT's Löb induction axioms, we are able to recover GuTT's type-based notion of fuel through the class of modalities for which $\langle \mu \mid \mathsf{acc} \rangle$. We then use this to derive Löb induction. Gatsby also offers a richer class of modalities than GuTT and in particular seamlessly includes $\Box$ which proved difficult for GuTT.

Clocked cubical type theory ($\mathsf{CloTT}_{\square}$) [25] also attempts to satisfy Thesis 1 but through very different means. Firstly, rather than including multiple interacting modalities, $\mathsf{CloTT}_{\square}$ includes only $\blacktriangleright$ but then *indexes* it by a clock κ which can be quantified over. The presence of clocks allows $\mathsf{CloTT}_{\square}$ to add Löb induction as an axiom which unfolds only in specific circumstances; roughly after the particular clock κ has been bound to prevent any further occurrences of $\blacktriangleright^{\kappa}$. Like Gatsby, $\mathsf{CloTT}_{\square}$ conjecturally satisfies canonicity and decidable type-checking and, like Gatsby, it therefore provisionally satisfies Goals 1 to 4.[2] However, the approach is very different.

$\mathsf{CloTT}_{\square}$'s indexed $\blacktriangleright$ modality offers a richer framework for guarded programming. However, clock quantification does not replicate all uses of $\square$ and forces a more complex semantics [29]. Moreover, clock quantification necessitates considering *clock-irrelevant* types, precluding a well-adapted theory of universes for guarded programming. On the other hand, while Gatsby enjoys a simpler semantics, richer modalities, and better-behaved universes, programming with modalities can be less intuitive than with clocks and clocks are required for nested guarded types. The biggest difference is in the approach Gatsby and $\mathsf{CloTT}_{\square}$ take for Löb induction. While $\mathsf{CloTT}_{\square}$ adds in Löb induction as an axiom and restricts its computation to decide type-checking, Gatsby *derives* Löb induction from modalities. In addition to the intrinsic interest of this decomposition, this approach arguably makes it easier to extend Gatsby with additional reasoning principles. Despite these differences, Gatsby has crucially benefited from the work behind $\mathsf{CloTT}_{\square}$: the $\mathsf{CloTT}_{\square}$ approach to clock-irrelevant types motivates our exploration of accessible types and the cubical variant of MTT [1] which Gatsby extends is inspired by $\mathsf{CloTT}_{\square}$.

1.4 Contributions

We present *guarded accessible type theory* or Gatsby: a modal type theory built on MTT extended with a new primitive computational modality $\top$. From this purely modal extension, we derive Löb induction and offer a complete solution to the problems of the original guarded dependent type theory proposed by Birkedal et al. [8].

- We show that Gatsby satisfies Goals 1 and 2 above and offer evidence for Goals 3 and 4.
- We show that more standard presentations of guarded recursion can be compiled faithfully into Gatsby.
- We demonstrate that Gatsby is usable by providing a pair of case-studies extending an example given by Birkedal et al. [8] and Clouston et al. [15].

Gatsby is the first guarded type theory to support computational Löb induction alongside the rich modal structure of $\mathbf{PSh}(\omega)$ $(\blacktriangleright, \blacktriangleleft, \square, \Diamond)$ without immediately precluding decidable type-checking. Moreover, the good behavior of universes and propositions in univalent foundations is critical to Gatsby, making it a novel application of homotopy type theory to programming languages.

While we have carried out our reconstruction of Löb induction by extending (cubical) MTT, the methodology is not tied to any particular modal type theory. We therefore see this reconstruction of Löb induction as a contribution independent of cubical MTT. Throughout this paper, however, we work with Gatsby both for concreteness and to evaluate the efficacy of our approach.

Organization. In Section 2 we introduce *cubical MTT*, the foundation of Gatsby. Section 3 introduces Gatsby itself and tours through its most essential features. Section 5 uses Gatsby to improve upon a logical-relations argument from Birkedal et al. [8]. Finally, Section 6 discusses the semantics of Gatsby and proves its soundness.

[2] The non-cubical variant of $\mathsf{CloTT}_{\square}$ [4] is known to enjoy normalization and satisfies Goals 1, 3 and 4. However, it does not include any means of proving $\mathsf{loeb}(f) = f(\mathsf{next}(\mathsf{loeb} f))$ and therefore does not satisfy Goal 2.

2 Cubical MTT and Guarded Recursion

Gatsby depends on a computational account of univalence and a well-behaved theory of modalities. In this section we recall some of the details of a system which contains both: Cubical MTT [1]. Cubical MTT is a variant on ordinary MTT in which every mode contains a copy of cubical type theory, as opposed to the ordinary copy of intensional Martin-Löf type theory. Fortunately, the details of cubical type theory are not essential to understanding Gatsby. The same cannot be said of the theory of modalities used by Gatsby where details do matter.

Accordingly, we will give a brief overview of MTT only, as the reader will be able to follow all the constructions of Sections 3 to 5 simply by assuming that Gatsby is built atop ordinary MTT extended with univalence; the only import of the cubical implementation of univalence is that it is computational.[3] We recall further details of cubical MTT in Section 6 where they are relevant.

For a comprehensive review of MTT we refer the reader to Gratzer [19, Chapter 6] or Gratzer et al. [22]. For cubical type theory and computational univalence, we suggest Cohen et al. [16].

A glossary for homotopy type theory. We will take advantage of a variety of standard notations and definitions from homotopy type theory. The standard reference for these is the HoTT Book [47].

For convenience, we recall that if $p : x = y$ then $\mathsf{transport}_B\, p : B\,x \to B\,y$. In the special case where $B = \mathsf{id}$, then we write p_* for the induced map. If $f : A \to B$ and $p : a_0 = a_1$, we write $\mathsf{ap}_f\, p$ for the induced path $f\, a_0 = f\, a_1$. We shall have frequent occasion to use the univalent version of propositions: homotopy proposition or hprop. An hprop is a type A equipped with a (necessarily unique) function $(a_0, a_1 : A) \to a_0 = a_1$. We write hProp_i for the subtype of the universe $\mathbf{U}_i$ spanned by hprops. We write $\|A\|$ for the unique homotopy proposition equipped with a map $\eta : A \to \|A\|$ such that $\eta^* : P^{\|A\|} \to P^A$ is an equivalence for all propositions P.

Finally, for convenience, we shall generally omit subscripts around universes and avoid discussing size issues. So we shall write $\mathbf{U} : \mathbf{U}$ and leave it to the reader to insert the subscripts $\mathbf{U}_i : \mathbf{U}_{i+1}$. This also applies to hProp_i for which we will simply write hProp.

2.1 A Summary of Multimodal Type Theory

To a first approximation, MTT is a machine which accepts as input an abstract specification of modalities (a *mode theory* [27]) and produces a modal type theory as output satisfying canonicity and normalization [18]. While generally, a mode theory is allowed to be a strict 2-category, for our purposes it suffices to consider a 1-category *enriched in partial orders*. That is, a mode theory is a category $\mathcal{M}$ where every hom-set $\hom_{\mathcal{M}}(x, y)$ is a partial order such that composition is monotone.

Suppose MTT is instantiated with some mode theory $\mathcal{M}$. The objects of $\mathcal{M}$ are called *modes* (ranged over by m, n, o) and the morphisms are *modalities* (ranged over by μ, ν, ξ). In MTT, each mode m yields a separate copy of type theory with its attendant set of judgments ($\vdash \Gamma\ \mathsf{cx}\ @\ m$, $\Gamma \vdash A\ \mathsf{type}\ @\ m$, etc.). Each type theory is then extended with several operations to reflect the modalities which link the modes:

$$
\begin{array}{llll}
\textit{(Cx)} & \Gamma, \Delta & ::= & \ldots \mid \Gamma.(\mu \mid A) \mid \Gamma.\{\mu\} \\
\textit{(Ty)} & A, B & ::= & \ldots \mid A[\gamma] \mid \langle \mu \mid A \rangle \mid (\mu \mid A) \to B \\
\textit{(Tm)} & M, N & ::= & \ldots \mid M[\gamma] \mid \mathbf{mod}_\mu(M) \mid \mathbf{let}_\nu\ \mathbf{mod}_\mu(-) \leftarrow M\ \mathbf{in}\ N \\
\textit{(Sb)} & \delta, \gamma & ::= & \ldots \mid \uparrow \mid \gamma.M \mid \gamma.\{\mu\} \mid \Gamma.\{\mu \le \nu\}
\end{array}
$$

The idea behind MTT is that each modality $\mu : n \longrightarrow m$ induces (1) a type former $\langle \mu \mid - \rangle$ sending mode n types to mode m types along with (2) a context former $-.\{\mu\}$ sending m contexts to n contexts. We add equations ensuring that $\Gamma.\{\mathsf{id}\} = \Gamma$ and $\Gamma.\{\nu\}.\{\mu\} = \Gamma.\{\nu\mu\}$. We note that

[3] We conjecture that an alternative account of computational univalence—e.g., the work by Shulman, Altenkirch, and Kaposi [42]—could be adapted for a similar purpose.

MTT feature *explicit substitutions* [30]. Such substitutions γ should be thought of as simultaneous substitutions and $A[\gamma]$ ($M[\gamma]$) represents the application of this substitution to a type A (a term M).

Roughly, $-.\{\mu\}$ is the *left adjoint* to $\langle \mu \mid - \rangle$; modalities in MTT are (weak) *dependent right adjoints* [6]. Hence, an element $\Gamma \vdash M : \langle \mu \mid A \rangle$ is roughly equivalent to an element $\Gamma.\{\mu\} \vdash N : A$. Converting N to M is the role of the introduction rule:

$$\frac{\Gamma.\{\mu\} \vdash A\,\mathsf{type} \mathbin{@} n}{\Gamma \vdash \langle \mu \mid A \rangle\,\mathsf{type} \mathbin{@} m} \qquad \frac{\Gamma.\{\mu\} \vdash M : A \mathbin{@} n}{\Gamma \vdash \mathbf{mod}_\mu(M) : \langle \mu \mid A \rangle \mathbin{@} m}$$

The passage from M to N is more fraught. The elimination principle ought to give such an inverse. Directly adding such an operation, however, disrupts the substitution property of the type theory. We instead add a "pattern-matching" elimination rule similar to the elimination principle used for booleans or natural numbers.

It is here that the modified form of context $\Gamma.(\mu \mid A)$ is used, so we postpone the elimination rule and first explain how this novel form of context extension works. Roughly, $\Gamma.(\mu \mid A)$ is a context with a variable of type A *annotated with* μ. While morally the same as an element of $\langle \mu \mid A \rangle$, the force of the annotation is the following rule used to pull a variable out from behind $\{\mu\}$:

$$\frac{\Gamma.\{\mu\} \vdash A\,\mathsf{type} \mathbin{@} n}{\Gamma.(\mu \mid A).\{\mu\} \vdash \mathbf{var} : A[\uparrow .\{\mu\}] \mathbin{@} m}$$

This is almost the standard variable rule for a type theory built using explicit substitution and de Bruijn indices, but with a few key differences. Most importantly, because the last variable in the context is μ-annotated, we can only access it when the context is restricted by $\{\mu\}$ (intuitively, $\{\mu\}$ *cancels* the μ annotation). Moreover, since A is a dependent type, we must mind the context in which it is well-formed: $\Gamma.\{\mu\}$. Since the conclusion of the variable rule is $\Gamma.(\mu \mid A).\{\mu\}$, we must construct an explicit substitution $\Gamma.(\mu \mid A).\{\mu\} \longrightarrow \Gamma.\{\mu\}$ to shift A from its original context to that of the conclusion. This is the role of $\uparrow .\{\mu\}$: $\uparrow$ is the weakening substitution and $-.\{\mu\}$ is a substitution former which sends a simultaneous substitution $\Gamma \vdash \delta : \Delta$ to $\Gamma.\{\mu\} \vdash \delta.\{\mu\} : \Delta.\{\mu\}$. The general rule for accessing the nth variable in a context is then built from **var** and the weakening substitution.

We now return to the original question of the elimination rule for $\langle \mu \mid A \rangle$. Intuitively, this rule ensures that it suffices to assume every element of $\langle \mu \mid A \rangle$ is of the form $\mathbf{mod}_\mu(-)$:

$$\frac{\begin{array}{cc} \nu : m \longrightarrow o & \Gamma.\{\nu\} \vdash M : \langle \mu \mid A \rangle \mathbin{@} m \\ \Gamma.(\nu \mid \langle \mu \mid A \rangle) \vdash B\,\mathsf{type} \mathbin{@} o & \Gamma.(\nu \circ \mu \mid A) \vdash N : B[\mathsf{id}.\mathbf{mod}_\mu(\mathbf{var})] \mathbin{@} o \end{array}}{\Gamma \vdash \mathbf{let}_\nu\ \mathbf{mod}_\mu(-) \leftarrow M\ \mathbf{in}\ N : B[\mathsf{id}.M] \mathbin{@} o}$$

$$\mathbf{let}_\nu\ \mathbf{mod}_\mu(-) \leftarrow \mathbf{mod}_\mu(M)\ \mathbf{in}\ N = N[\mathsf{id}.M]$$

MTT includes a normal dependent function type $(x : A) \to B(x)$ which is written $A \to B$ in keeping with the name-free syntax. However, in order to account for modalities it is frequently helpful to use a dependent function type which internalizes not just $x :_{\mathsf{id}} A$ (the ordinary case), but also allows one to hypothesize over modal variables $x :_\mu A$. This essentially codifies the common pattern of accepting an element of $\langle \mu \mid A \rangle$ as an argument and immediately pattern-match on it. To

this effect, we add the following rules:

$$\frac{\mu : n \longrightarrow m \qquad \Gamma \vdash A\,\mathsf{type} \mathbin{@} n \qquad \Gamma.(\mu \mid A) \vdash B\,\mathsf{type} \mathbin{@} m}{\Gamma \vdash (\mu \mid A) \to B\,\mathsf{type} \mathbin{@} m}$$

$$\frac{\Gamma.\{\mu\} \vdash A\,\mathsf{type} \mathbin{@} n \qquad \Gamma.(\mu \mid A) \vdash M : B \mathbin{@} m}{\Gamma \vdash \lambda M : (\mu \mid A) \to B \mathbin{@} m}$$

$$\frac{\Gamma.\{\mu\} \vdash N : A \mathbin{@} n \qquad \Gamma \vdash M : (\mu \mid A) \to B \mathbin{@} m}{\Gamma \vdash M(N) : B[\mathsf{id}.N] \mathbin{@} m}$$

Only one new feature remains to be discussed in the type theory. This is the explicit substitution $\Gamma.\{\mu \le \nu\}$ which integrates the mode theories partial order into the type theory:

$$\frac{\vdash \Gamma\,\mathsf{cx} \qquad \mu \le \nu}{\Gamma.\{\nu\} \vdash \Gamma.\{\mu \le \nu\} : \Gamma.\{\mu\} \mathbin{@} m}$$

In practice, this substitution is used to use a μ-annotated variable beneath $\{\nu\}$. In particular, using this variable rule, we can justify the following principle:

$$\frac{\Gamma.\{\mu\} \vdash A\,\mathsf{type} \mathbin{@} n \qquad \mu \le \nu}{\Gamma.(\mu \mid A).\{\nu\} \vdash \mathbf{var}[\Gamma.\{\mu \le \nu\}] : A[\uparrow.\{\mu\} \circ \Gamma.\{\mu \le \nu\}] \mathbin{@} m}$$

Thus far we have favored precision while introducing MTT and therefore used de Bruijn indices and explicit substitutions. This is particular important when specifying modal type theories, as substitution is often subtle and non-standard. However, the above rule shows that it can become quite cumbersome to insist on using de Bruijn indices and so hereafter we switch to named variables and more standard informal type theory.

When writing MTT terms "informally", we will write $x :_\mu A$ to indicate the variable x exists in the context with annotation μ and type A. If $\mu = \mathsf{id}$, we suppress it to recover the traditional notation. We therefore are able to suppress weakening substitutions as well as $\Gamma.\{\mu \le \nu\}$ when writing terms e.g., the above rule would simply become $\Gamma, x :_\mu A, \{\nu\} \vdash x : A$. We refer the reader to Gratzer [19, Section 6.1] for a detailed discussion of this point. Paralleling the ordinary notation for dependent products, we write $(x :_\mu A) \to B(x)$ for the informal version of $(\mu \mid A) \to B$.

2.2 Instantiating MTT with $\mathcal{M}_{\mathbf{Gatsby}}$

We now turn from MTT in general to its instantiation with the specific mode theory required for Gatsby as detailed in Fig. 1. The mode theory is a combination of mode theories previously used to adapt MTT to study guarded recursion [19–21].

Unlike many presentations of guarded recursion, it contains multiple modes. The types at mode t are intended to behave like objects from $\mathbf{PSh}(\omega)$ and can exhibit guarded behavior, while s is intended to capture $\mathbf{Set}$. Each modality μ is intended to capture a particular right adjoint F_μ on or between these categories:

$$F_\ell(X) = \blacktriangleright X \qquad F_e(X) = \blacktriangleleft X \qquad F_\delta(S) = \lambda n.\, S \qquad F_\gamma(X) = \lim_\omega X \qquad F_{\epsilon_0}(X) = X(0)$$

$$F_\top(X) = \{\star\}$$

See Birkedal et al. [8] for the definitions of $\blacktriangleleft$ and $\blacktriangleright$ on $\mathbf{PSh}(\omega)$. Inspired by the above, we will write $\blacktriangleright A \triangleq \langle \ell \mid A \rangle$, $\blacktriangleleft A \triangleq \langle e \mid A \rangle$, $\Box A \triangleq \langle \delta \circ \gamma \mid A \rangle$, and $\Diamond A \triangleq \langle \delta \circ \epsilon_0 \mid A \rangle$.

Remark 2.1. In MTT, modalities $\langle \mu \mid - \rangle$ apply only to types in context $\Gamma.\{\mu\}$. Accordingly, $\blacktriangleright = \langle \ell \mid - \rangle$ automatically induces a map $\blacktriangleright \mathbf{U} \to \mathbf{U}$ as was seen in e.g., Birkedal and Møgelberg [7].

Remark 2.2. For the sake of simplicity, we have chosen to ignore the complications imposed by modeling cubical MTT and interpreting univalence above. In Section 6 we shall return to this point and show that the preceding sketch can be turned into a valid construction by replacing sets with cubical sets and presheaves with cubical presheaves. For the next two sections we shall ignore univalence when providing semantic intuitions and simply note that all arguments can be adapted to cubical sets with minimal changes.

Several modal combinators are definable for any modality in MTT and, when appropriately instantiated, these yield familiar operations in guarded recursion. In particular, we shall have use for the following general MTT combinators:

$$\circledast : \langle \mu \mid A \to B \rangle \to \langle \mu \mid A \rangle \to \langle \mu \mid B \rangle \qquad \mathsf{distr} : \langle \mu \mid A \times B \rangle \simeq \langle \mu \mid A \rangle \times \langle \mu \mid B \rangle$$

$$\mathsf{triv} : \langle \mathsf{id} \mid A \rangle \simeq A \qquad \mathsf{comp} : \langle \nu \mid \langle \mu \mid A \rangle \rangle \simeq \langle \nu \circ \mu \mid A \rangle \qquad \mathsf{coe}_{\mu \leq \nu} : \langle \mu \mid A \rangle \to \langle \nu \mid A \rangle$$

For instance, the standard map $\mathsf{next} : A \to \blacktriangleright A$ is defined as $\mathsf{coe}_{\mathsf{id} \leq \ell} \circ \mathsf{triv}^{-1}$ and the equivalence $\mathsf{now} : \Box\blacktriangleright A \simeq \Box A$ is realized by comp. We record these and more in an omni-bus theorem:

Theorem 2.3.

(1) $\blacktriangleright$ *is a well-pointed applicative functor,*
(2) $\Box$ *is an idempotent comonad and* $\Box\blacktriangleright \simeq \Box \simeq \Box\blacktriangleleft$,
(3) *the following pairs are adjoint:* $\blacktriangleleft \dashv \blacktriangleright$, $\Diamond \dashv \Box$, $\langle \delta \mid - \rangle \dashv \langle \gamma \mid - \rangle$, *and* $\langle \epsilon_0 \mid - \rangle \dashv \langle \delta \mid - \rangle$.

We emphasize that certain modalities, $\blacktriangleleft$ and $\langle \delta \mid - \rangle$, are *left adjoint* modalities. These modalities enjoy particularly good behavior in MTT in the form of a variety of *crisp induction principles* [19, 40]. For instance, $\langle \delta \mid \mathbf{Bool} \rangle$ is equivalent to **Bool** and we may therefore perform induction on an element of the former as if it were the latter.[4] This is not the case for every modality $\langle \mu \mid - \rangle$. However, inductive types are preserved by left adjoint modalities, and we capitalize on this fact several times.

Finally, we note two specific consequences of working with cubical MTT rather than ordinary MTT. First, as already mentioned, each mode supports the univalence axiom. Second, each modality preserves identity types:

Theorem 2.4. *The map* $\mathbf{mod}_\mu(a) = \mathbf{mod}_\mu(b) \to \langle \mu \mid a = b \rangle$ *sending* **refl** *to* $\mathbf{mod}_\mu(\mathbf{refl})$ *is an equivalence. We denote the inverse map* $\iota : \langle \mu \mid a = b \rangle \to \mathbf{mod}_\mu(a) = \mathbf{mod}_\mu(b)$.

Corollary 2.5. *The map* $\langle \mu \mid A \to B \rangle \to (\langle \mu \mid A \rangle \to \langle \mu \mid B \rangle)$ *restricts to a map* $\langle \mu \mid A \simeq B \rangle \to (\langle \mu \mid A \rangle \simeq \langle \mu \mid B \rangle)$.

2.3 A No-Go Theorem for Löb Induction

Thus far we have avoided any mention of Löb induction. Indeed, as an instantiation of cubical MTT, our theory thus far cannot possibly validate Löb induction without additional axioms. We now give a proof of this no-go theorem which implies that no choice of mode theory makes Löb induction derivable in an instantiation of MTT without additional axioms.

Theorem 2.6 (No-go)**.** *For any* $\mathcal{M}$ *and* $\mu \in \mathcal{M}$, *there is no term* $(\langle \mu \mid \mathbf{Void} \rangle \to \mathbf{Void}) \to \mathbf{Void}$ *in cubical MTT instantiated with* $\mathcal{M}$.

[4] For **Nat**, we add this crisp induction principle directly, but this does not impact the metatheory [19]

Proof. MTT with mode theory $\mathcal{M}$ has a model where each mode is interpreted by ordinary (cubical) type theory and each modality is realized by the identity. If $(\langle \mu \mid \mathbf{Void} \rangle \to \mathbf{Void}) \to \mathbf{Void}$ was derivable in (cubical) MTT, then interpreting this term into this model would yield an element of $(\llbracket \mathbf{Void} \rrbracket \to \llbracket \mathbf{Void} \rrbracket) \to \llbracket \mathbf{Void} \rrbracket$ in (cubical) type theory for each A in MTT. Since $\llbracket \mathbf{Void} \rrbracket = \mathbf{Void}$ (the empty type), we would have $M : (\mathbf{Void} \to \mathbf{Void}) \to \mathbf{Void}$ and so $M(\mathrm{id}) : \mathbf{Void}$; this contradicts the soundness of cubical type theory. □

3 Introducing Gatsby

In Section 2 we introduced (cubical) MTT and discussed its instantiation to $\mathcal{M}_{\text{Gatsby}}$. As it stands, this instantiation must be extended with a new rule in order to validate Löb induction (Theorem 2.6). We now present this new rule (Rule 1) and show that it forces $\langle \top \mid A \rangle = \mathbf{Unit}$. We term the system extended with it Gatsby.

A priori, constraining $\top$ in this manner is entirely unrelated to Löb induction. We prove, however, that the interactions between $\top$ and other modalities in the system give us the ability to *define* Löb induction on a large class of types. We carry out this derivation in stages; we define a homotopy proposition which entails Löb induction (Theorem 3.5) and then show that this homotopy proposition holds in certain circumstances (Theorem 3.7). In Sections 3.3 and 3.4, we then show how to parlay this new reasoning principle into a workable guarded type theory.

3.1 The New Rule

As shown in Theorem 2.6, the key obstruction to deriving Löb induction is that we cannot guarantee that $\blacktriangleright$ (or indeed any of our modalities) is not actually the identity. In order to rule this out, we shall add a new rule forcing one modality, $\top$, to be not the identity. To do this, note that $\langle \top \mid A \rangle$ is intended to encode **Unit** and so its left adjoint action $\Gamma.\{\top\}$ corresponds to extending Γ by the empty type. In particular, $\Gamma.\{\top\}$ will be interpreted by the empty set. With this in mind, we add the following rule:

$$\frac{\Gamma \vdash r : \mathbf{1}.\{\top\} \mathbin{@} s}{\Gamma \vdash \mathcal{J}} \tag{1}$$

In the above, $\mathcal{J}$ ranges over any judgment. Intuitively, if there exist a substitution from Γ to $\mathbf{1}.\{\top\}$, then Γ will be interpreted by the empty set as well and so the principle of explosion ought to let us conclude any judgment we wish in this context.

Remark 3.1. This rule is similar to the rule in cubical type theory stating that $\Gamma \vdash \mathcal{J}$ holds if Γ proves the false cofibration [16].

While we phrased this rule in an algebraic way by asking for a substitution from the context to $\mathbf{1}.\{\top\}$, we can prove that it is decidable whether such a substitution exists (see Theorem 8.1). Such a metatheorem is crucial for showing that Gatsby admits a normalization algorithm. Indeed, similar rules yield undecidable type theories because of the absence of such a result.

Lemma 3.2. *Rule 1 implies* $\langle \top \mid A \rangle = \mathbf{Unit}$.

Proof. First, we note that $\langle \top \mid A \rangle$ is inhabited. Indeed, to construct an element of $\langle \top \mid A \rangle$, it suffices to construct an element of A in a context restricted by $\{\top\}$ but Rule 1 ensures this is true regardless of A. By univalence, it then suffices to argue that all elements in $\langle \top \mid A \rangle$ are equal. While one can argue directly, this is an immediate consequence of Theorem 2.4 and the argument above after replacing A by $a_0 =_A a_1$. □

In light of this result, we say that $\langle \top \mid - \rangle$ is a *computational* modality [24]. On its own, constraining $\langle \top \mid A \rangle$ to be **Unit** is not a useful change. After all, if we only cared about constraining $\langle \top \mid A \rangle$

we could simply discard the modal apparatus and take this equivalence to be an equality. The force of this extension comes through the interactions between $\top$ and other modalities. In particular, $\epsilon_0 \circ \ell = \top \circ \epsilon_0$ together with Lemma 3.2 implies the following:

$$\langle \epsilon_0 \mid \blacktriangleright A \rangle = \mathbf{Unit}$$

While this is obviously true in the model (the first stage of $\blacktriangleright X$ is $\{\star\}$ by definition), it is only after forcing $\langle \top \mid A \rangle = \mathbf{Unit}$ that we can derive this result purely within the theory. Having some circumstances under which $\blacktriangleright A$ trivializes opens up a new avenue to encoding Löb induction.

3.2 The Accessible Proposition

Contrary to prior guarded type theories, we will not endeavor to make Löb induction directly available on each type at mode t. We will instead split things up into two steps:

(1) Define an (h-)proposition acc which implies Löb induction.
(2) Prove that $\langle \mu \mid \mathsf{acc} \rangle$ holds for a large class of modalities μ.

This two-step approach offers a way to include Löb induction in Gatsby without directly postulating it. Instead, when working with guarded recursion we will *assume* acc holds, such that the type of the end result will be $\mathsf{acc} \to A$. In order to actually run such a program, we then choose an appropriate modality μ and switch to considering $\langle \mu \mid \mathsf{acc} \to A \rangle$. The general principles of MTT modalities together with our proof of $\langle \mu \mid \mathsf{acc} \rangle$ then enables us to conclude $\langle \mu \mid A \rangle$. By choosing μ appropriately, we are then able to extract arbitrary finite approximations of A and compute with Löb induction without ever directly postulating it. While the first step can be carried out in ordinary MTT, showing that $\langle \mu \mid \mathsf{acc} \rangle$ is true for any modality requires Gatsby's computational $\top$ modality.

The proposition acc is defined using the truncation modality $\|-\|$ from homotopy type theory:

Definition 3.3. We define $\mathsf{acc} = \left\| \sum_{n:\mathbf{Nat}} \blacktriangleright^n \mathbf{Void} \right\|$ at mode t.

Remark 3.4. Note that acc is globally true when t is interpreted into $\mathbf{PSh}(\omega)$ where it is realized by $\exists n.\, \blacktriangleright^n \bot$. In this model, $\blacktriangleright^n \bot$ has a more recognizable form as the representable presheaf $\mathbf{y}(n)$. From this viewpoint, acc is equivalent to the join of all $\mathbf{y}(n)$ which is $\mathbf{1}$ by construction. However, while it holds in the intended model, it is not derivable within Gatsby. For instance, one could interpret mode t using $\mathbf{Sh}(\omega^2)$ where acc is not globally true; it circumscribes the open embedding of $\mathbf{PSh}(\omega)$ into $\mathbf{Sh}(\omega^2)$.

We now set out to prove that assuming acc is sufficient to derive Löb induction. Intuitively, as acc states that there exists some n such that $\blacktriangleright^n \mathbf{Void}$ holds, we ought to be able to define $\mathsf{loeb}(f) : A$ where $f : \blacktriangleright A \to A$ by induction on n; if $n = 0$ then we use the now modality-free assumption of **Void** and otherwise we apply f to an element of $\blacktriangleright A$ which we obtain through our induction hypothesis. Unfortunately, this naïve proof strategy does not work: the propositional truncation used to define acc means that we cannot directly scrutinize n when constructing an element of A. However, we may strengthen our goal slightly to work around this issue.

Instead of constructing $\mathsf{loeb}(f) : A$, we could instead construct an element $\mathsf{loeb}(f) : A$ together with a proof that $\mathsf{loeb}(f)$ is a guarded fixed-point i.e., $f(\mathsf{next}(\mathsf{loeb}\, f)) = \mathsf{loeb}\, f$. Indeed, while there are potentially many distinct elements of A, we prove that f has at most one guarded fixed-point. We will therefore prove that the type of guarded fixed-points of f is *contractible* (inhabited and all inhabitants are equal). This type is a hprop and so it is valid to scrutinize an element of acc when proving it. We emphasize that this strategy relies heavily on the good behavior of homotopy propositions in univalent foundations.

Theorem 3.5. *In mode t, for any $A : \mathbf{U}$ and $f : \blacktriangleright A \to A$ there exists a term* $\mathsf{gfix} : \mathsf{acc} \to \mathsf{isContr}(\mathsf{GFix}\, A\, f)$ *where* $\mathsf{GFix}\, A\, f$ *is the type of guarded fixed-points* $\sum_{a:A} f(\mathsf{next}\, a) = a$.

Proof. We take advantage of the fact that isContr is a proposition to ignore the truncation on acc and actually scrutinize the underlying natural number. We define gfix as follows:

$$\begin{aligned}
&\mathsf{gfix}\ \|(0,p)\| = \mathsf{absurd}\ p\\
&\mathsf{gfix}\ \|(1+n, \mathbf{mod}_\ell(p))\| = \ ?0 : \mathsf{isContr}(\mathsf{GFix}\ f)\\
&\quad \textbf{where}\\
&\qquad C :_\ell \mathsf{isContr}(\mathsf{GFix}\ f)\\
&\qquad C = \mathsf{gfix}\ \|(n,p)\|\ f
\end{aligned}$$

Note that the ℓ-annotation on C prevents us from using this variable to immediately fill $?0$. Indeed, this would correspond to defining $\mathsf{gfix}\ \cdots = \mathsf{gfix}\ \ldots$, which is precisely the sort of non-productive recursion guarded types are meant to preclude. Instead, we start with a preliminary observation: given any element of $\blacktriangleright\mathsf{GFix}\ f$ (or, equivalently, an ℓ-annotated element of $\mathsf{GFix}\ f$), we may promote it to an element of $\mathsf{GFix}\ f$.

$$\begin{aligned}
&\mathsf{promote} : (r_\ell :_\ell \mathsf{GFix}\ f) \to \textstyle\sum_{r:\mathsf{GFix}\ f} \blacktriangleright(r = r_\ell)\\
&\mathsf{promote}\ (a,p) = \textbf{let}\ r = (f(\mathbf{mod}_\ell(a)), \mathsf{ap}_f(\iota(\mathbf{mod}_\ell(p))))\ \textbf{in}\\
&\quad (r, \mathbf{mod}_\ell(\ \{\ell\} \vdash ?1 : r = (a,p)\ ))
\end{aligned}$$

Note that in the above, we have used ι from Theorem 2.4. To fill $?1$, it suffices to fill the following:

$$\{\ell\} \vdash ?2 : f(\mathsf{next}(a)) = a$$

$$\{\ell\} \vdash ?3 : \mathsf{ap}_f(\iota(\mathsf{next}\ p)) = ?2 \bullet p \bullet \mathsf{ap}_{f\circ\mathsf{next}}(?2^{-1})$$

The choice for $?2$ is clear enough: p^{-1}. Plugging this in, it suffices to construct a term of the following type:

$$\{\ell\} \vdash \mathsf{ap}_f(\iota(\mathsf{next}\ p)) = \mathsf{ap}_{f\circ\mathsf{next}}(p)$$

This follows immediately from the definition of ι.

Next, we note that $\pi_1(\mathsf{promote}\ r) = r$. We again have two holes to fill if we let $r = (a,p)$:

$$?4 : f(\mathsf{next}(a)) = a$$

$$?5 : \mathsf{ap}_f(\iota(\mathsf{next}\ p)) = ?2 \bullet p \bullet \mathsf{ap}_{f\circ\mathsf{next}}(?2^{-1})$$

A similar argument fills these two holes with $?4 = p^{-1}$.

We now return to $?0$. It suffices to implement the following:

$$?6 : \mathsf{GFix}\ f \qquad ?7 : (r : \mathsf{GFix}\ f) \to\ ?6\ = r$$

We fill $?6 = \mathsf{promote}(\pi_1 C)$. For the second hole, we use our remark that $r = \mathsf{promote}\ r$ together with $\pi_2 C$, transitivity, and ι. □

We can derive Löb induction from gfix:

$$\begin{aligned}
&\mathsf{loeb} : (A : \mathbf{U}) \to ((\ell \mid A) \to A) \to \mathsf{acc} \to A\\
&\mathsf{loeb}\ A\ f\ z = \pi_1(\pi_1(\mathsf{gfix}\ A\ (\lambda x.\ \textbf{let}\ \mathbf{mod}_\ell(x_\ell) \leftarrow x\ \textbf{in}\ f\ x_\ell)\ z))
\end{aligned}$$

$$\begin{aligned}
&\mathsf{unfold} : (A : \mathbf{U})(f : (\ell \mid A) \to A) \to \mathsf{acc} \to f(\mathsf{next}(\mathsf{loeb}\ f)) = \mathsf{loeb}\ f\\
&\mathsf{unfold}\ A\ f\ z = \pi_2(\pi_1(\mathsf{gfix}\ A\ (\lambda x.\ \textbf{let}\ \mathbf{mod}_\ell(x_\ell) \leftarrow x\ \textbf{in}\ f\ x_\ell)\ z))
\end{aligned}$$

Remark 3.6. We note that we have required loeb accept a modal function $(\ell \mid A) \to A$ rather than $\blacktriangleright A \to A$. This is a useful convenience as it allows us to shorten the otherwise ubiquitous $\mathsf{loeb}(\lambda x.\ \textbf{let}\ \mathbf{mod}_\ell(-) \leftarrow x\ \textbf{in}\ x_\ell \ldots)$ to simply $\mathsf{loeb}(\lambda x.\ \ldots)$. The types $\blacktriangleright A \to A$ and $(\ell \mid A) \to A$ are equivalent, however, so this is only a matter of convenience.

While this is certainly interesting, if we can never discharge the acc assumption from gfix, this brings us no closer to ever being able to actually use these combinators. While we cannot prove acc holds on its own, we can show that $\langle \epsilon_0 \circ e^n \mid \mathsf{acc} \rangle$ holds. We break this statement apart into two results:

Theorem 3.7. *The following hold in modes t and s respectively:*

- $\blacktriangleleft \mathsf{acc} = \mathsf{acc}$
- $\langle \epsilon_0 \mid \mathsf{acc} \rangle = \mathbf{Unit}$

Proof. For the first point, we note that $\blacktriangleleft$ is a left adjoint and therefore commutes with both propositional truncation and natural numbers [19, Lemmas 6.4.16 and 6.4.15]. By propositional univalence, it therefore suffices to show that acc implies the following:

$$\left\| \textstyle\sum_{m:\mathbf{Nat}} \blacktriangleleft \blacktriangleright^m \mathbf{Void} \right\|$$

Scrutinizing our assumption of acc, we know that there exists some k such that $\blacktriangleright^k \mathbf{Void}$; we then choose $m = k + 1$ to obtain the goal.

For the second claim, we switch to working in mode s. As all modalities in Gatsby preserve identity types and the unit, they preserve homotopy levels and, in particular, h-props. It therefore suffices to show that $\langle \epsilon_0 \mid \mathsf{acc} \rangle$ holds at all and we shall accomplish this by arguing that $\left\langle \epsilon_0 \mid \sum_{n:\mathbf{Nat}} \blacktriangleright^n \mathbf{Void} \right\rangle$ holds. Commuting this modality with the dependent sum, it suffices to argue that $\langle \epsilon_0 \mid \blacktriangleright \mathbf{Void} \rangle$ holds. However, we have shown in the prior subsection that $\langle \epsilon_0 \mid \blacktriangleright \mathbf{Void} \rangle = \langle \top \mid \langle \epsilon_0 \mid \mathbf{Void} \rangle \rangle = \mathbf{Unit}$. □

Corollary 3.8. *For* $n : \mathbf{Nat}$ *we have* $\langle \epsilon_0 \mid \blacktriangleleft^n \mathsf{acc} \rangle = \mathbf{Unit}$.

In particular, if we confine ourselves to just working in mode t, we will not be able to (dis)prove acc and so loeb cannot be run. However, if we write a closed program e.g. $M : \mathsf{acc} \to \blacktriangleright^n \mathbf{Nat}$, we can place the entire program under $\langle \epsilon_0 \mid \blacktriangleleft^n - \rangle$ and discharge the acc assumption to obtain a program of type $\langle \epsilon_0 \mid \blacktriangleleft^n \blacktriangleright^n \mathbf{Nat} \rangle \simeq \mathbf{Nat}$. Intuitively, the choice of n allows us to internally recover a type-based "fuel" discipline for running guarded programs. We explore this process in the next two sections.

3.3 The Universe of Accessible Types

The previous subsection outlined an approach for guarded recursion in Gatsby: hypothesize acc when constructing a program and discharge it for closed terms using modalities. However, this simple strategy has two major drawbacks. First, it is hardly convenient to manually thread the acc assumption through every program we write. Second, it may not even be possible to do so! Working in a modal type theory, some connectives restrict access to the context and so we may write a program which assumes acc in the beginning and yet find ourselves unable to rely on this assumption midway through the program having descended beneath $\Box$ or $\blacktriangleright$.

The solution to both of these problems is the same: rather than manually passing around acc, we should consistently work with the acc-null types. That is, types A such that the canonical map $A \to (\mathsf{acc} \to A)$ is an equivalence. Informally, these are the types that "do not care" if a finite number of steps remain. By restricting attention to these types, we free ourselves of the requirement to pass acc around manually; whenever we require a witness for acc we can simply "pull it out" of the goal A by replacing it with $\mathsf{acc} \to A$.

This has another startling consequence: if we limit ourselves to working with accessible types, we never need to mention or explicitly discharge acc. Each accessible type knows how to remove the acc and we shall see that this allows the process to fade into the background.

Definition 3.9. We say a type is accessible if it is acc-null. The universe of accessible types $\mathbf{U}_{\mathrm{acc}}$ is therefore written as follows:

$$\mathbf{U}_{\mathrm{acc}} = \textstyle\sum_{A:\mathbf{U}} \mathsf{isEquiv}(\mathsf{const} : A \to (\mathsf{acc} \to A))$$

This is a subuniverse of $\mathbf{U}$; the map $\mathbf{U}_{\mathrm{acc}} \to \mathbf{U}$ is an embedding.

If we restrict gfix, loeb, and unfold to applications where A belongs to $\mathbf{U}_{\mathrm{acc}}$ rather than $\mathbf{U}$, we may dispense with the acc hypothesis e.g., $\mathsf{loeb} : (A : \mathbf{U}_{\mathrm{acc}}) \to ((\ell \mid A) \to A) \to A$. This leads us to ask what structure $\mathbf{U}_{\mathrm{acc}}$ possess and which types are accessible.

The universe of accessible types is a *reflective subuniverse* [39]. We therefore conclude a number of results about $\mathbf{U}_{\mathrm{acc}}$ from op. cit.

Proposition 3.10 (Rijke et al. [39])**.**

(1) $\mathbf{U}_{\mathrm{acc}}$ *is spanned by* $\bigcirc$*-modal types where* $\bigcirc A = \mathsf{acc} \to A$.
(2) $\mathbf{U}_{\mathrm{acc}}$ *is closed under dependent products and sums, the unit type, and identity types.*
(3) $\mathbf{U}_{\mathrm{acc}}$ *and* $\mathsf{hProp}_{\mathrm{acc}}$*—the subtype of* $\mathbf{U}_{\mathrm{acc}}$ *spanned by hProps—are accessible types.*
(4) $\bigcirc$ *is a lex idempotent monad (in fact, an* open modality[5]*).*

Moreover, $\mathbf{U}_{\mathrm{acc}}$ *is a model of HoTT and* $\bigcirc$ *a morphism of models.*

We will not reproduce the entire proof for reasons of space, but we will show the argument for why $\mathbf{U}_{\mathrm{acc}}$ is accessible. We highlight this because it relies crucially upon univalence and is one place where working with cubical MTT over ordinary MTT is vital.

Proof. We claim that $\eta : \mathbf{U}_{\mathrm{acc}} \to \bigcirc\mathbf{U}_{\mathrm{acc}}$ is an equivalence. By another result of Rijke et al. [39, Lemma 1.20], it is sufficient to construct a left inverse to η. That is, we must define $r : \bigcirc\mathbf{U}_{\mathrm{acc}} \to \mathbf{U}_{\mathrm{acc}}$ such that for all $A : \mathbf{U}_{\mathrm{acc}}$, $r(\eta\, A) = A$. We define r as follows:

$$r\, \tilde{A} = (z : \mathsf{acc}) \to \tilde{A}\, z$$

To show that this is a left inverse, we must show that if $A : \mathbf{U}_{\mathrm{acc}}$ then $A = \mathsf{acc} \to A$. By univalence, it suffices to show that there is an equivalence $A \simeq \mathsf{acc} \to A$. We conclude by noting that const is such an equivalence because $A : \mathbf{U}_{\mathrm{acc}}$. □

We note that it is crucial that acc be in hProp for Proposition 3.10 to hold: if we did not truncate acc, we could not prove that $\mathsf{acc} \to -$ was an *idempotent* monad and we would therefore be unable to prove that $\mathbf{U}_{\mathrm{acc}}$ is itself acc-modal. This, in turn, would cause us to lose access to a hierarchy of acc-modal universes of acc-modal types.

The universe of accessible types $\mathbf{U}_{\mathrm{acc}}$ enjoys a number of additional closure properties, specifically due to the behavior of acc. In particular, $\mathbf{U}_{\mathrm{acc}}$ is closed under both $\Box$ and $\blacktriangleright$, and we can prove these facts purely within Gatsby without additional assumptions.

Theorem 3.11.

(1) *If* $A :_{\ell} \mathbf{U}_{\mathrm{acc}}$ *then* $\blacktriangleright A$ *is accessible.*
(2) *If* $A :_{\delta} \mathbf{U}$ *then* $\langle \delta \mid A \rangle$ *is accessible.*

In particular, $\Box A : \mathbf{U}_{\mathrm{acc}}$ *for all* A *and* $\blacktriangleright$ *induces a map* $\blacktriangleright\mathbf{U}_{\mathrm{acc}} \to \mathbf{U}_{\mathrm{acc}}$.

Proof. We begin with the first statement. Suppose that $A :_{\ell} \mathbf{U}_{\mathrm{acc}}$. We note that $\blacktriangleright$ is a right adjoint modality and employ the transposition equivalence proven by Gratzer [19, Lemma 6.4.2]:

$$\mathsf{acc} \to \blacktriangleright A \simeq \blacktriangleright(\blacktriangleleft\mathsf{acc} \to A)$$

[5]There is an unfortunate terminological clash here; Rijke et al. [39] use the term modality to refer to lex idempotent monads while Gratzer et al. [21] use it to refer to $\langle \mu \mid - \rangle$. For us, modality is meant in the latter sense.

By Theorem 3.7, $\blacktriangleleft\mathrm{acc} = \mathrm{acc}$ and we therefore continue:

$$\blacktriangleright(\blacktriangleleft\mathrm{acc} \to A) \simeq \blacktriangleright(\mathrm{acc} \to A) \simeq \blacktriangleright A$$

The last step follows from Corollary 2.5 applied to $\mathbf{mod}_\ell(\pi_2 A) : \blacktriangleright(A \simeq (\mathrm{acc} \to A))$. This proves that $\blacktriangleright A \simeq (\mathrm{acc} \to \blacktriangleright A)$ and computation shows that the induced equivalence is the constant map.

The second statement is similar, since $\langle \delta \mid - \rangle$ is right adjoint to ϵ_0 and we have already shown that $\langle \epsilon_0 \mid \mathrm{acc} \rangle = \mathbf{Unit}$ (Corollary 3.8):

$$\mathrm{acc} \to \langle \delta \mid A \rangle \simeq \langle \delta \mid \langle \epsilon_0 \mid \mathrm{acc} \rangle \to A \rangle \simeq \langle \delta \mid A \rangle$$

Computation shows that the inverse to this chain of equivalences is the constant map. □

Corollary 3.12. *Both* **Nat** *and* **Bool** *are accessible and if* $A, B : \mathbf{U}_{\mathrm{acc}}$ *then* $A + B$ *is also accessible.*

Proof. As δ is a left adjoint, $\langle \delta \mid \mathbf{Nat} \rangle = \mathbf{Nat}$ and $\langle \delta \mid \mathbf{Bool} \rangle = \mathbf{Bool}$. The second statement follows by noting that Σ and **Bool** suffice to define $+$ and $\mathbf{U}_{\mathrm{acc}}$ is closed under both. □

This corollary, which is a direct consequence of Lemma 3.2, is essential for ensuring that $\mathbf{U}_{\mathrm{acc}}$ is usable. Absent this result, $\mathbf{U}_{\mathrm{acc}}$ would still be closed under a large collection of operations but contain no non-trivial base types. However, since essentially all connectives and base types do land in $\mathbf{U}_{\mathrm{acc}}$, we are able to perform all standard operations in mode t and stay within $\mathbf{U}_{\mathrm{acc}}$, without ever mentioning non-accessible types.

For instance, we may construct the type of guarded streams featured in the introduction without explicitly threading acc through the construction. We simply replace $\mathbf{U}$ with $\mathbf{U}_{\mathrm{acc}}$ to ensure that we are applying Löb induction to an accessible type:

$$\mathrm{GStr} = \mathrm{loeb}(\lambda S.\mathbf{Nat} \times \blacktriangleright S)$$

Here we have taken advantage of the fact that $\mathbf{U}_{\mathrm{acc}}$ is closed under both **Nat** and $\times$. The propositional unfolding associated with Löb induction also ensures that $\mathrm{GStr} = \mathbf{Nat} \times \blacktriangleright \mathrm{GStr}$.

In fact, we can codify this procedure more generally:

Theorem 3.13 (Completeness)**.** *Any program written in MLTT with* $\blacktriangleright$, $\Box$, *and* loeb *with propositional unfolding can be compositionally encoded in Gatsby such that the standard connectives of MLTT except universes are realized by precisely the same operations in Gatsby.*

Proof. We must construct a model of such a type theory in Gatsby. We do so by interpreting types as accessible types—thereby interpreting Löb induction. We then use Proposition 3.10, Theorem 3.11, and Corollary 3.12 to interpret all connectives. □

Inaccessible Types. Care is required when working with types such as propositional truncation $\|-\|$ which do not preserve accessibility. For instance, acc itself is not accessible in all models (if it were, then acc would simply be true) but acc is the propositional truncation of the type $\sum_{n:\mathbf{Nat}} \blacktriangleright^n \mathbf{Void}$ which is always accessible. Consequently, $\|-\|$ does not induce a map $\mathbf{U}_{\mathrm{acc}} \to \mathbf{U}_{\mathrm{acc}}$.

If we wish to use $\|A\|$ in a guarded program, it would be necessary to explicitly replace it by the accessible type $\|A\|' = \mathrm{acc} \to \|A\|$. This cannot cause issues within the program itself: mapping out of $\|A\|'$ to an accessible type is the same as mapping out of $\|A\|$. However, after the construction is completed and one wishes to inspect the results as an ordinary type, it is necessary to record that the replacement has taken place. In such situations we must use Corollary 3.8 ourselves. After obtaining a closed term $M : \mathrm{acc} \to \|A\|$, we must choose some natural number n and consider $\mathbf{mod}_{\epsilon_0 \circ e^n}(M) \circledast \star : \langle \epsilon_0 \circ e^n \mid \|A\| \rangle$. Choosing different numbers n enables us to extract different finite approximations of $\|A\|$. This may be important if e.g., $A = \blacktriangleright^k A_0$ so that the first stages of $\|A\|$ are trivial. This corresponds to the idea of type-based fuel introduced by Gratzer and Birkedal [20].

Thus, it is possible, if more complex, to apply guarded reasoning to types which are not accessible. Fortunately, the standard operations of type theory and guarded recursion $(\Box, \blacktriangleright)$ *do* land in $\mathbf{U}_{\mathrm{acc}}$ so this occurs infrequently.

3.4 First Examples in Gatsby

We begin by working through some elementary constructions in guarded type theory in order to give a flavor of working within the system. We begin by filling in the details of Example 1.2:

$$\begin{aligned}&\mathsf{GStr} : \mathbf{U}_{\mathrm{acc}} \to \mathbf{U}_{\mathrm{acc}}\\ &\mathsf{GStr}\, A = \mathsf{loeb}(\lambda S.\, A \times \blacktriangleright S)\end{aligned}$$

$$\begin{aligned}&\mathsf{GStrEq} : (A : \mathbf{U}_{\mathrm{acc}}) \to \mathsf{GStr}\, A = A \times \blacktriangleright \mathsf{GStr}\, A\\ &\mathsf{GStrEq}\, A = \mathsf{unfold}(\lambda S.\, A \times \blacktriangleright S)\end{aligned}$$

We emphasize that we are able to use loeb and unfold in the above definitions because our goal is produce an inhabitant of $\mathbf{U}_{\mathrm{acc}}$ which by Proposition 3.10 is accessible. Moreover, by construction, $\mathsf{GStr}\, A$ is an accessible type—it is an inhabitant of $\mathbf{U}_{\mathrm{acc}}$—and so we are able to use Löb induction when construction guarded streams.

We demonstrate how one might carry out small but complete guarded program which first (1) calculates an infinite stream of Fibonacci numbers and then (2) extracts the third number. We begin by defining the stream of numbers using Löb induction:

$$\begin{aligned}&\mathsf{fibs} : \mathsf{GStr}\, \mathbf{Nat}\\ &\mathsf{fibs} = \mathsf{go}\, 0\, 1\\ &\quad \textbf{where}\\ &\qquad \mathsf{go} : \mathbf{Nat} \to \mathbf{Nat} \to \mathsf{GStr}\\ &\qquad \mathsf{go} = \mathsf{loeb}(\lambda f.\, \lambda m, n.\, (\mathsf{GStrEq}\, \mathbf{Nat})^{-1}_{*}(m, \mathbf{mod}_{\ell}(f\, n\, (m+n))))\end{aligned}$$

Notice that in this example, $(\mathsf{GStrEq}\, A)^{-1}_{*}$—coercing backwards along the equation $\mathsf{GStr}\, A = A \times \blacktriangleright \mathsf{GStr}\, A$—plays the role of cons. We record this: $\mathsf{cons}_A = (\mathsf{GStrEq}\, A)^{-1}_{*} : A \times \blacktriangleright \mathsf{GStr}\, A \to \mathsf{GStr}\, A$. Deconstructing a stream uses the inverse coercion i.e., $\mathsf{hd} = \pi_1 \circ (\mathsf{GStrEq}\, A)_{*}$ and $\mathsf{tl} = \pi_2 \circ (\mathsf{GStrEq}\, A)_{*} : \mathsf{GStr}\, A \to \blacktriangleright \mathsf{GStr}\, A$.

To extract the third element, we must bring $\Box$ into play. In particular, in order to obtain an element of type **Nat** rather than $\blacktriangleright^2\mathbf{Nat}$, we will use the equivalence $\Box\blacktriangleright A \simeq \Box A$. We note that both $\mathsf{GStr}\, \mathbf{Nat}$ and fibs are closed terms and we may form the following:

$$\begin{aligned}&\mathsf{fibs}' : \Box(\mathsf{GStr}\, \mathbf{Nat})\\ &\mathsf{fibs}' = \mathbf{mod}_{\delta\circ\gamma}(\mathsf{fibs})\end{aligned}$$

We then use $\mathsf{now} : \Box\blacktriangleright A \simeq \Box A$ and $\mathsf{extract} : \Box A \to A$ to pull out the third element:

$$\begin{aligned}&\mathsf{third} : \mathbf{Nat}\\ &\mathsf{third} = \textbf{let}\ \mathbf{mod}_{\delta\circ\gamma}(s) \leftarrow \mathsf{fibs}'\ \textbf{in}\ \mathsf{extract}(\mathsf{now}(\mathsf{now}(\mathsf{go}\, s)))\\ &\quad \textbf{where}\\ &\qquad \mathsf{go} : (\delta \circ \gamma \mid \mathsf{GStr}\, \mathbf{Nat}) \to \Box\blacktriangleright\blacktriangleright\mathbf{Nat}\\ &\qquad \mathsf{go}\, s = \mathbf{mod}_{\delta\circ\gamma}(\mathsf{next}(\mathsf{next}\, \mathsf{hd}) \circledast (\mathsf{next}\, \mathsf{tl} \circledast \mathsf{tl}\, s))\end{aligned}$$

We note that under the assumption of canonicity for Gatsby (Section 8.1), we can compute third and obtain a closed natural number. Thus, in particular, purely through careful use of modalities, we are able to derive Löb induction and use it to compute a closed result. Even without the assumption of canonicity, we are able to use unfold to prove that $\mathsf{third} = 1$.

To cultivate intuition, let us consider a pair of counterfactuals. Suppose that we had worked within a theory without Rule 1, what would have changed in the above example? The main difference would be in the behavior of **Nat**: without Rule 1, **Nat** would not land in $\mathbf{U}_{\mathrm{acc}}$. We could replace it

with acc $\to$ **Nat** and the rest of the calculation would proceed along the same lines. However, the final result would have type acc $\to$ **Nat**. Without Theorem 3.7, there would be no way to discharge that hypothesis. Next, suppose instead that we considered a type theory without univalence but with a good theory of propositions, such as extensional type theory. In this case, we would not be able to show $\mathbf{U}_{\text{acc}}$ to be accessible. More ad-hoc replacements are possible, for instance acc $\to$ **U**, but these alternatives will (1) not form a cumulative hierarchy and (2) not admit an embedding into **U** without additional axioms. This hinders the construction of elements of GStr.

4 Case Study with Coinductive Types

In this section, we show how Gatsby can capitalize on guarded recursion to prove statements purely about types in mode s. That is, users of Gatsby can state theorems purely within ordinary cubical type theory and prove them with arguments which use guarded recursion. Concretely, we show how Löb induction in mode t can be used to obtain coinductive types in mode s.

For simplicity, we will limit our view to the type of coinductive streams, but this proof-technique scales to produce *terminal coalgebras* (coinductive types) for a wide array of functors. For the remainder of this section, let us (1) work within mode s and (2) fix $A : \mathbf{U}$. Our goal shall be to construct the type of coinductive streams of elements of A.

We begin by crystallizing the requirements for such a type.

Definition 4.1. An A-stream coalgebra is a pair of $X : \mathbf{U}$ along with $\theta_X : X \to A \times X$. A homomorphism of stream algebras $(X, \theta_X) \to (Y, \theta_Y)$ is a function $f : X \to Y$ such that $A \times f \circ \theta_X = \theta_Y \circ f$.

Definition 4.2. The type of coinductive streams of elements of A is coalgebra (S, θ_S) such that (S, θ_S) is the *terminal object* in the category of A-stream coalgebras.

We note that, roughly, θ_S encodes the *destructor* of the stream while the property that it is the terminal coalgebra encodes coinduction. We can already have enough machinery in place to give the definition of the (putative) type of streams using the already defined type of guarded streams:

$$\begin{aligned}&\mathsf{Str} : \mathbf{U}\\ &\mathsf{Str} = \langle \gamma \mid \mathsf{GStr}\, \langle \delta \mid A \rangle \rangle\end{aligned}$$

$$\begin{aligned}&\theta : \mathsf{Str} \to A \times \mathsf{Str}\\ &\theta\, s = \mathbf{let}\ \mathbf{mod}_\gamma(s) \leftarrow s\ \mathbf{in}\ (\mathbf{mod}_\gamma(\mathsf{hd}\, s), \mathsf{now}(\mathbf{mod}_\gamma(\mathsf{tl}\, s)))\end{aligned}$$

It therefore remains only to show that (Str, θ) is the terminal stream coalgebra. To this end, let us fix an arbitrary coalgebra (X, θ_X). It suffices to show that there is a unique homomorphism $(X, \theta_X) \to (\mathsf{Str}, \theta)$. Let us begin by observing that to produce a map from $X \to \mathsf{Str} = \langle \gamma \mid \mathsf{GStr}\, \langle \delta \mid A \rangle \rangle$, it suffices to construct an element of $\langle \gamma \mid \langle \delta \mid X \rangle \to \mathsf{GStr}\, \langle \delta \mid A \rangle \rangle$. Furthermore, such an element $f :_\gamma \langle \delta \mid X \rangle \to \mathsf{GStr}$ transposes to a coalgebra homomorphism if and only if it satisfies the following equation:

$$\langle \gamma \mid (\langle \delta \mid A \rangle \times (\mathsf{next} \circ f)) \circ \mathsf{distr} \circ (\mathbf{mod}_\delta(\theta_X) \circledast -) = f \rangle \tag{2}$$

Lemma 4.3. *There is a unique element of* $\langle \gamma \mid \langle \delta \mid X \rangle \to \mathsf{GStr} \rangle$ *satisfying Eq. (2).*

Proof. For this proof, let us work in mode t once more. We wish to show that there is a unique element of the following type:

$$\textstyle\sum_{f : \langle \delta | X \rangle \to \mathsf{GStr}} f = \lambda x.\, \mathbf{let}\ \mathbf{mod}_\delta((a, x)) \leftarrow \mathbf{mod}_\delta(\theta_X) \circledast x\ \mathbf{in}\ (a, \mathsf{next}(f\, x))$$

Inspecting this equation, however, we notice that this actually precisely a guarded definition of f: an operator $F : \blacktriangleright(\langle \delta \mid X \rangle \to \mathsf{GStr}) \to \langle \delta \mid X \rangle \to \mathsf{GStr}$ such that $f = F(\mathsf{next}(f))$:

$$F\, f = \lambda x.\, \mathbf{let}\ \mathbf{mod}_\delta((a, x)) \leftarrow \mathbf{mod}_\delta(\theta_X) \circledast x\ \mathbf{in}\ (a, f \circledast \mathsf{next}(x))$$

Moreover, since GStr is accessible, there is a unique solution to this problem and this is precisely our required unique homomorphism. □

Stitching this result together, we conclude the following:

Theorem 4.4. (Str, θ) *is the type of coinductive streams of elements of* A.

While this is certainly a toy example, we emphasize that we were able to use accessibility and Löb induction to prove a theorem within mode s without any of these details leaking into the theorem statement. In other words, a user of e.g., cubical Agda [49] extended to support Gatsby could use Theorem 4.4 without having to know or understand the details of Löb induction. Moreover, even though GStr was defined using Löb induction on $\mathbf{U}_{\mathrm{acc}}$ and therefore involved various constructions on this subuniverse (some involving univalence!) none of those precluded seamlessly using GStr to define a type in mode s.

The above proof is similar to that given by Møgelberg [34] in the context of clocked type theory, though with a few minor differences. Most importantly, because Gatsby has only a single $\blacktriangleright$ modality unlike op. cit., we must ensure that the type A is itself constant when constructing Str. We are able to cleanly encode this using the separation between modes s and t: the construction of Str induces a map $\mathbf{U} \to \mathbf{U}$ *in mode* s and therefore cannot be applied to types where this problem might arise.

5 Case Study with Logical Relations

In this section, we present a case-study of Gatsby by using it to construct a (synthetically) step-indexed Kripke logical relation for an ML-like language $\lambda_{\mathrm{ref},\forall}$ with general references (pointers to complex structures) and parametric polymorphism. We then use it to deduce semantic type-safety. This $\lambda_{\mathrm{ref},\forall}$ language and the logical relation is based on the account given by Birkedal et al. [8, Section 3] but our more advanced type theory allows us to improve upon their results in two respects:

(1) We do not need to worry about local contractibility of domain equations because we have access to a universe and solve the domain equation as an ordinary fixed point [7].
(2) We have no need to carry out a challenging external argument after constructing the logical relation because Gatsby is multimodal. Accordingly, we work internally to Gatsby throughout the entire proof.

We have chosen this example to "complete the story" started by Birkedal et al. [8], but quite a few other applications of guarded type theory to denotational semantics and logical relations exist [11, 12, 32, 33, 35, 38, 45, 46, 48]. Many of these applications can also be simplified in light of Gatsby's richer modal apparatus.

For reasons of space, we have included only selected details of this case study. In particular, where there is little difference from working in Gatsby versus the framework of Birkedal et al. [8], we have avoided duplicating their work.

Impredicativity and propositional resizing. In order to construct a logical relation for $\lambda_{\mathrm{ref},\forall}$, we require an impredicative universe of propositions, something which is not directly included in Gatsby. The reasons for this inclusion are essentially twofold: first, to employee Girard's *method of candidates* to account for impredicative type quantification through $\forall$ and second, to allow for the *worlds* in the Kripke logical relation to contain non-syntactic predicates on locations. For this particular setting, we could simply dispense with $\forall$ and focus on a more syntactic definition of worlds. However, both simplifications would make the logical relation a less realistic case study and so we instead include an axiom to force hProp_0 to become our desired impredicative universe.

In what follows we shall assume *propositional resizing* and, in particular, assert that the canonical map $\mathsf{hProp}_0 \to \mathsf{hProp}_1$ is an equivalence. We expect this axiom to be validated by our intended

model and provide evidence for this in Remark 6.8. However, adding propositional resizing as an axiom to Gatsby will certainly disrupt canonicity. More broadly, it is not known within ordinary cubical type theory whether propositional resizing admits a computational interpretation at all. Accordingly, the current state of affairs for resizing in cubical type theory is similar to classical logic: it can be soundly postulated without disrupting the decidability of type-checking, but at the cost of canonicity. We expect the same state of affairs for Gatsby which suffices for our purposes in this case study; we do not need to 'compute' with the logical relation we are constructing.

5.1 Static and Dynamic Semantics of $\lambda_{\mathsf{ref},\forall}$

We begin by defining $\lambda_{\mathsf{ref},\forall}$, the language under consideration. We specify this language in mode s, i.e., with no guarded recursion whatever. As we shall argue in Section 6, this ensures that our definition of $\lambda_{\mathsf{ref},\forall}$ adequately represents the standard definition that one might formalize in Coq or similar.

We define the syntax of (untyped) terms and types as inductive types. We then define term and type contexts (TCxt, Cxt) and heaps (Heap) on top of these. The typing judgments as well as the operational semantics are realized by inductively-defined propositions:

$$\begin{aligned}
&\mathsf{isCx} : \mathsf{TCxt} \to \mathsf{Cxt} \to \mathsf{hProp}\\
&\mathsf{isTy} : \mathsf{TCxt} \to \mathsf{Ty} \to \mathsf{hProp}\\
&\mathsf{hasTy} : (\Xi : \mathsf{TCxt}) \to \mathsf{Cxt}^{\mathsf{wf}}\,\Xi \to \mathsf{Tm} \to \mathsf{Ty}^{\mathsf{wf}}\,\Xi \to \mathsf{hProp}\\
&\mathsf{isVal} : \mathsf{Tm} \to \mathsf{hProp}\\
&(\mapsto) : \mathsf{Tm} \times \mathsf{Heap} \to \mathsf{Tm} \times \mathsf{Heap} \to \mathsf{hProp}
\end{aligned}$$

We sketch all of these definitions in Fig. 2, using informal BNF grammars to specify the syntax of terms and types and inference rules for the judgments. We leave implicit many details as they are orthogonal to our case study and refer the reader to Birkedal et al. [8]. We have also assumed the existence of various standard operations on lists, such as snoc, lookup, etc. We do note that we formalize heaps as a list of values and that allocation is deterministic. Moreover, primitive locations $\mathtt{loc}(\ell)$ are never well-typed; they arise only in intermediate stages of execution for programs and are never written by a user.

We will write $\mapsto^*$ for the reflexive transitive closure of $\mapsto$. As in Birkedal et al. [8], we have opted to present the operational semantics with deterministic allocation as this simplifies a number of technical details. We shall write $\mathsf{Good} : \mathsf{Tm} \times \mathsf{Heap} \to \mathsf{hProp}$ for the following:

$$\begin{aligned}
&\mathsf{canStep}(e,h) = \exists e', h'.\,(e,h) \mapsto (e',h')\\
&\mathsf{Good}\,e\,h = \forall (e',h').\,((e,h) \mapsto^* (e',h')) \to \mathsf{isVal}\,e' \vee \mathsf{canStep}(e',h')
\end{aligned}$$

In other words, a configuration consisting of an expression and a heap is good if one can execute the pair for an arbitrary number of steps and the resulting expression and heap has either resulted in a value or can be run further. Our goal for the remainder of this section is to prove the following version of type-safety.

Theorem 5.1 (Safety of $\lambda_{\mathsf{ref},\forall}$)**.** *If* $\mathsf{isTm}\,0\,\mathsf{nil}\,e\,\tau$ *then* $\mathsf{Good}\,e\,\mathsf{nil}$

We note that the presence of $\mathtt{loc}(\ell)$ makes this theorem more difficult to prove. We could extend the type system to account for the occurrences of $\mathtt{loc}(\ell)$ that arise in intermediate stages, but we will explore a more robust proof methodology.

5.2 A Unary Logical Relation Interpretation

In order to prove Theorem 5.1, we will construct a model of $\lambda_{\mathsf{ref},\forall}$ which interprets $\lambda_{\mathsf{ref},\forall}$ types as elements of a construction in mode t. Morally, the construction is a Kripke logical relation, but the presence of higher-order references necessitates a rich and highly-recursive type of worlds. It is for

$$\begin{array}{lll} \tau : \mathsf{Ty} & ::= & \mathtt{tvar}(i) \mid \mathtt{Ref}(\tau) \mid \mathtt{forall}(\tau) \mid \tau \times \tau \mid \ldots \\ e : \mathsf{Tm} & ::= & \mathtt{var}(i) \mid !e \mid \mathtt{new}(e) \mid \mathtt{set}(e, e) \mid \Lambda e \mid e[\tau] \mid \ldots \end{array}$$

$$\mathsf{TCxt} = \mathbf{Nat} \qquad \mathsf{Cxt} = \mathsf{List}\,\mathsf{Ty} \qquad \mathsf{Cxt}^{\mathsf{wf}}\,\Xi = \textstyle\sum_{\Gamma:\mathsf{Cxt}} \mathsf{isCxt}\,\Xi\,\Gamma \qquad \mathsf{Ty}^{\mathsf{wf}}\,\Xi = \textstyle\sum_{\tau:\mathsf{Ty}} \mathsf{isTy}\,\Xi\,\tau$$

$$\mathsf{Val} = \textstyle\sum_{e:\mathsf{Tm}} \mathsf{isVal}\,e \qquad\qquad \mathsf{Heap} = \mathsf{List}\,\mathsf{Val}$$

$$\frac{\mathsf{isTm}(\Xi, \Gamma, e, \tau)}{\mathsf{isTm}(\Xi, \Gamma, \mathtt{new}(e), \mathtt{Ref}(\tau))} \qquad \frac{\mathsf{isTm}(\Xi, \Gamma, e, \mathtt{Ref}(\tau))}{\mathsf{isTm}(\Xi, \Gamma, !e, \tau)}$$

$$\frac{\mathsf{isTm}(\Xi, \Gamma, e_1, \mathtt{Ref}(\tau)) \qquad \mathsf{isTm}(\Xi, \Gamma, e_2, \tau)}{\mathsf{isTm}(\Xi, \Gamma, \mathtt{set}(e_1, e_2), \tau)}$$

$$\begin{array}{rcll} (\mathtt{new}(v), h) & \mapsto & (\mathtt{loc}(\mathsf{len}\,h), \mathsf{snoc}(h, v)) & \\ (!\mathtt{loc}(\ell), h) & \mapsto & (\mathsf{lookup}(h, \ell), h) & (\ell < \mathsf{len}\,h) \\ (\mathtt{set}(\mathtt{loc}(\ell), v), h) & \mapsto & (v, \mathsf{replace}(h, \ell, v)) & (\ell < \mathsf{len}\,h) \end{array}$$

Fig. 2. Selected rules of $\lambda_{\mathsf{ref},\forall}$

this reason that we must pass to mode t, where Löb induction is available; we shall use it to define the semantic universe of types alongside the worlds indexing them.

$$\begin{array}{l} \mathcal{P}\,A = A \to \mathsf{hProp}_{\mathsf{acc}} \\ \mathsf{W} : \mathbf{U}_{\mathsf{acc}} \qquad (\sqsubseteq) : \mathsf{W} \to \mathsf{W} \to \mathsf{hProp}_{\mathsf{acc}} \\ (\mathsf{W}, \sqsubseteq) = \mathsf{loeb}(\lambda A, \le .\, (\mathsf{X}(A, \le), \mathsf{R}(A, \le))) \\ \quad \textbf{where} \\ \qquad \mathsf{X}\,(A, \le) = \mathbf{Nat} \to_{\mathsf{fin}} ((\blacktriangleright A, \le^{\dagger}) \to_{\mathsf{mon}} (\mathcal{P}\langle \delta \mid \mathsf{Val}\rangle, \subseteq)) \\ \qquad \mathsf{R}\,(A, \le)\,w_1\,w_2 = \forall \ell. w_1(\ell)\downarrow \to w_1\ell = w_2\ell \\ \mathsf{T} : \mathbf{U}_{\mathsf{acc}} \\ \mathsf{T} = \mathsf{W} \to_{\mathsf{mon}} \mathcal{P}\langle \delta \mid \mathsf{Val}\rangle \end{array}$$

Notation 5.2. We follow Gratzer [19] in writing $\mathsf{foo}^{\dagger}$ to lift a function or relation foo to apply to a sequence of modal arguments similar to *idiom brackets* for applicative functors [31].

A few words of discussion are in order. First, $\to_{\mathsf{mon}}$ refers to the subtype of monotone maps where $\mathcal{P}\langle \delta \mid \mathsf{Val}\rangle$ is ordered by subset inclusion. To use W in the domain of $\to_{\mathsf{mon}}$, we must define W simultaneously with its ordering relation $\sqsubseteq$. For this reason, we use Löb induction to compute an element of $\sum_{A:\mathbf{U}_{\mathsf{acc}}} A \to A \to \mathsf{hProp}_{\mathsf{acc}}$ rather than merely $\mathbf{U}_{\mathsf{acc}}$. Second, $\to_{\mathsf{fin}}$ refers to finitely-supported partial maps. We note that this procedure is simpler than its cousin in Birkedal et al. [8]: we have access to a universe and therefore have no need to use an external construction.

The remaining details of the unary logical relation proceed along similar lines to Birkedal et al. [8], though we are able to simplify several definitions by continuing to exploit the internal language. We define a path WEq witnessing the unfolding of W to its definition using unfold. Next, we note that since $\langle \delta \mid - \rangle$ is a left adjoint, we have a crisp induction principle available and we use this to define a map $[\![-]\!]_- : \langle \delta \mid \mathsf{Ty}^{\mathsf{wf}}\,\Xi\rangle \to \left(\sum_{n \le \Xi} \mathsf{T}\right) \to \mathsf{T}$ for each $\Xi : \langle \delta \mid \mathsf{TCxt}\rangle = \langle \delta \mid \mathbf{Nat}\rangle = \mathbf{Nat}$. This map sends a type with Ξ free variables to a map from Ξ semantic types to a single semantic type. The details of $[\![-]\!]_-$ are not vital, but the following auxiliary definitions will be important later:

$$\begin{aligned}
&\mathsf{sat}\, w\, h = \\
&\quad \mathsf{dom}(h) \subseteq \mathsf{dom}(w) \wedge \forall \ell \in \mathsf{dom}(w).\mathsf{WEq}_*\, w\, \ell\, w\, (\mathsf{lookup}^\dagger\, h\, \ell)
\end{aligned}$$

$$\begin{aligned}
&\mathsf{comp} : \mathsf{T} \to \mathsf{W} \to \mathcal{P}\langle \delta \mid \mathsf{Exp}\rangle \\
&\mathsf{comp}\, \phi\, w\, e = \\
&\quad (\mathsf{isVal}^\dagger\, e \wedge \phi\, w\, e) \\
&\quad \vee \forall h : \langle \delta \mid \mathsf{Heap}\rangle.\, \mathsf{sat}\, w\, h \to \\
&\qquad \exists e' h' w'.\, (e, h) \mapsto^\dagger (e', h') \wedge w \sqsubseteq w' \wedge \mathsf{sat}\, w'\, h' \wedge \blacktriangleright \mathsf{comp}\, \phi\, e'\, w'
\end{aligned}$$

Informally, comp lifts ϕ to a predicate on expressions which evaluates the expression and, if it ever reaches a value, insists the result satisfies ϕ.[6] The following is proven as in Birkedal et al. [8].

Lemma 5.3 (Fundamental lemma)**.** *If* $\mathsf{isTm}^\dagger\, 0\, \mathsf{nil}\, e\, \tau$ *holds in mode* t *then so does* $\mathsf{comp}\, [\![\tau]\!]\, (\mathsf{WEq}_*\, \emptyset)\, e$.

5.3 Adequacy

At this point, we substantially deviate from Birkedal et al. [8]. It remains to argue that Lemma 5.3 implies Theorem 5.1. In op. cit., the authors were forced to unfold various definitions externally and argue that Lemma 5.3 externally implied the desired type-safety result. Our richer modal apparatus allows us to proceed internally. First, we note that Lemma 5.3 can be placed under $\langle \gamma \mid - \rangle$ (it is closed). Fixing e and τ in mode s, general properties of modalities yield the following implication:

$$\begin{aligned}
&\langle \gamma \mid \mathsf{isTm}^\dagger\, 0\, \mathsf{nil}\, \mathbf{mod}_\delta(e)\, \mathbf{mod}_\delta(\tau)\rangle \\
&\quad \to \langle \gamma \mid \mathsf{comp}\, [\![\mathbf{mod}_\delta(\tau)]\!]\, (\mathsf{WEq}_*\, \emptyset)\, \mathbf{mod}_\delta(e)\rangle
\end{aligned}$$

Inspecting the definitions, we note that the domain of this function is equal to $\mathsf{isTm}\, 0\, \mathsf{nil}\, e\, \tau$. It therefore remains only to show that the codomain implies $\mathsf{Good}\, e\, \mathsf{nil}$. In fact, in our case we do not need to worry about the actual properties of the value e runs to, so we will consider $\langle \gamma \mid \mathsf{comp}\, (\lambda\_.\, \mathbf{Unit})\, (\mathsf{WEq}_*\, \emptyset)\, \mathbf{mod}_\delta(e)\rangle$ instead.

We prove the following helper lemma in mode t.

Lemma 5.4. *If* $\mathsf{comp}\, (\lambda\_.\, \mathbf{Unit})\, w\, e$*, fix an* $h : \langle \delta \mid \mathsf{Heap}\rangle$ *such that* $\mathsf{sat}\, w\, h$ *and, moreover, if* $(e, h)\ (\mapsto^n)^\dagger\ (e', h')$ *then* $\blacktriangleright^n(\mathsf{isVal}^\dagger\, e' \vee \mathsf{canStep}^\dagger(e', h'))$.

Proof. We proceed by induction on n—which we can due to crisp induction. The base case where $(e, h) = (e', h')$ is trivial. For the inductive step, we may apply the induction hypothesis to reduce to the case that $(e, h) \mapsto (e', h')$. Noting that e must not be a value, we deduce that the following holds:

$$\exists e_1 h_1 w'.\, (e, h) \mapsto^\dagger (e_1, h_1) \wedge w \sqsubseteq w' \wedge \mathsf{sat}\, w'\, h_1 \wedge \blacktriangleright \mathsf{comp}\, \phi\, e_1\, w'$$

As our operational semantics are deterministic, we replace e_1, h_1 with e', h' and simplify the above:

$$\exists w' \sqsupseteq w.\, \mathsf{sat}\, w'\, h' \wedge \blacktriangleright \mathsf{comp}\, \phi\, e'\, w'$$

The goal then follows by unfolding the definition of comp. □

We may now return to mode s to complete the theorem.

Theorem 5.1 (Safety of $\lambda_{\mathsf{ref},\forall}$)**.** *If* $\mathsf{isTm}\, 0\, \mathsf{nil}\, e\, \tau$ *then* $\mathsf{Good}\, e\, \mathsf{nil}$

[6] We note that we did not need to define comp using Löb induction, though we certainly could have. Its definition is positive, however, and so Tarski's fixed-point theorem applies. The unicity of guarded fixed points, morover, ensures both approaches agree.

Proof. Fix e', h', n such that $(e, h) \mapsto^n (e', h')$. We must show that either $\mathsf{isVal}\, e'$ or $\mathsf{canStep}(e', h')$. By Lemma 5.3, we know that $\langle \gamma \mid \mathsf{comp}\ (\lambda\_.\ \mathbf{Unit})\ w\ \mathbf{mod}_\delta(e) \rangle$ holds. Using Lemma 5.4, we therefore obtain the following:

$$\langle \gamma \mid \blacktriangleright^n (\mathsf{isVal}^\dagger\, e' \vee \mathsf{canStep}^\dagger(e', h')) \rangle$$

Using the equation $\gamma \circ \ell = \gamma$, we may replace this:

$$\langle \gamma \mid (\mathsf{isVal}^\dagger\, e' \vee \mathsf{canStep}^\dagger(e', h')) \rangle$$

$\langle \gamma \mid - \rangle$ does not commute with disjunctions. However, $\langle \delta \mid - \rangle$ does commute with disjunctions as it is a left adjoint. We then replace the type under $\langle \gamma \mid - \rangle$ with $\langle \delta \mid \mathsf{isVal}\, e' \vee \mathsf{canStep}(e', h') \rangle$. We conclude using the equation $\gamma \circ \delta = \mathsf{id}$. □

We note that such a proof is impossible without $\langle \gamma \mid - \rangle$ or something equivalent to it; without such a feature we would have no means to remove the $\blacktriangleright^n$ appearing in Lemma 5.4.

6 Semantics of Gatsby

Thus far we have shown that Gatsby is usable but we not yet shown it to be sound. In this section, we prove this, among other results, by developing the model theory of Gatsby. This is seemingly daunting: constructing models of cubical type theory is already a challenging task. Fortunately Gatsby is built atop cubical MTT, which already has a well-developed denotational semantics [1].

At a high level, we wish to interpret mode t as $\mathbf{PSh}(\omega)$ and s as $\mathbf{Set}$, but this will not serve if we wish to interpret univalence. Instead, we must replace $\mathbf{Set}$ with the category of cubical sets $\mathbf{cSet}$. Beyond this change, we are able to interpret the modalities as right adjoints between these two categories without change. We thereby obtain a pseudofunctor $F : \mathcal{M}_{\mathsf{Gatsby}} \to \mathbf{Cat}$ which sends $F(s) = \mathbf{cSet}$ and $F(t) = \mathbf{PSh}_{\mathbf{cSet}}(\omega)$ (cubical presheaves on ω). We show the definitions of F on the generating 1-cells below:

$$F(\ell)\, X\, n = \mathsf{if}\ n = 0\ \mathsf{then}\ \mathbf{1}\ \mathsf{else}\ X(n-1) \qquad F(e)\, X\ = X(n+1) \qquad F(\gamma)\, X = \lim_{\omega} X$$

$$F(\epsilon_0)\, X = X(0) \qquad F(\delta)\, S\, n = S \qquad F(\top)\, S = \mathbf{1}$$

In general, cubical presheaves $\mathbf{PSh}_{\mathbf{cSet}}(C)$ (presheaves valued in cubical sets) support a model of cubical type theory [26]. The following result of Aagaard et al. [1] shows that these models of cubical type theory can be combined into a model of cubical MTT:

Proposition 6.1 (Theorem 4.15 [1])**.** *Fix a strict 2-functor $f : \mathcal{M} \longrightarrow \mathbf{Cat}$ and for each $\mu : n \longrightarrow m$, write $F^*(\mu) \dashv F_*(\mu)$ for the adjunction between $\mathbf{PSh}_{\mathbf{cSet}}(f(n))$ and $\mathbf{PSh}_{\mathbf{cSet}}(f(m))$ induced by pre-composition and right Kan extension. There is a model of cubical MTT with mode theory $\mathcal{M}$ which interprets $\langle \mu \mid - \rangle$ as $F_*(\mu)$ and where all monomorphisms are cofibrations.*[7]

Ideally, we would instantiate this theorem by taking $\mathcal{M} = \mathcal{M}_{\mathsf{Gatsby}}$ and define f in such a way that F is induced by right Kan extending f. Unfortunately, we cannot simply take this theorem off-the-shelf: not every functor described by F can be interpreted using right Kan extension. In particular, ϵ_0 and $\top$ do not arise in this way. Fortunately, $F(\epsilon_0)$ and $F(\top)$ "almost" arise from right Kan extension: their left adjoints preserve connected limits which suffices. We can therefore replay the proof of Proposition 6.1 from Aagaard et al. [1] nearly verbatim to obtain the following:

Lemma 6.2. *There exists a model of cubical MTT with mode theory $\mathcal{M}_{Gatsby}$ which interprets $\langle \mu \mid - \rangle$ using $F(\mu)$ and where all monomorphisms are cofibrations.*

[7] This last point is a technical condition necessary only for Corollary 6.6.

Proof Sketch. Unlike the rest of the paper, in this proof we will presuppose familiarity with the contents of Aagaard et al. [1]. We shall explain only the necessary adjustments to adapt Proposition 6.1 to prove Theorem 6.3 and refer the reader to Aagaard et al. [1] for all other details. To begin with, we explicitly construct the strict 2-functor $\bar{F} : \mathcal{M}_{\text{Gatsby}}{}^{\text{coop}} \to \mathbf{Cat}$ given by taking left adjoints of F:

$$\bar{F}(\ell)\, X\, n = X(n+1) \qquad \bar{F}(e)\, X\, n = X(\mathsf{pred}(n)) \qquad \bar{F}(\gamma)\, S\, n = S \qquad \bar{F}(\delta)\, X = X(0)$$

$$\bar{F}(\epsilon_0)\, S = \mathsf{if}\ n = 0\ \mathsf{then}\ S\ \mathsf{else}\ \mathbf{0} \qquad \bar{F}(\top)\, S = \mathbf{0}$$

We next note that in our model, we shall force all monomorphisms to be cofibrations and, accordingly, the *cofibration classifier* in both $\mathbf{PSh}_{\mathbf{cSet}}(\omega)$ and **cSet** is given by the ordinary subobject classifier. We further note that the interval object in both cases is given by the representable presheaves $\mathbf{y}([1])$ where $[1]$ is the generating object of the cube category $\square$ where $\mathbf{cSet} = \mathbf{PSh}(\square)$.

The heart of the model is to specify how these cofibrations and the interval object interact with modalities. Concretely, for each modality μ and semantic context Γ we must construct the following:

(1) a coherent choice of morphisms (a) $\bar{F}(\mu)(\mathbb{I}) \to \mathbb{I}$ and (b) $\bar{F}(\mu)(\Omega) \to \Omega$ which respect (a) De Morgan algebra structure and (b) bounded distributive lattice structure as well as quantification of $\mathbb{I}$.
(2) Coherent isomorphisms $\Gamma.\{\mu\}.\mathbb{I} \cong \Gamma.\mathbb{I}.\{\mu\}$
(3) If $\phi : \Gamma \to \Omega$, coherent isomorphisms $\Gamma.\{\mu\}.\bar{\phi} \cong \Gamma.\phi.\{\mu\}$ where $\bar{\phi}$ is induced by (1.b).

The argument given by Aagaard et al. [1] shows that for any modality μ interpreted by right Kan extension, (1.a), (2) may be realized by the identity. For (1.b), it suffices to note that if $\bar{F}(\mu)$ is given by right Kan extension, its left adjoint $\bar{F}(\mu)$ preserves monomorphisms and therefore (1.b) is canonically defined such that (3) is realized by the identity—this is the universal property of the subobject classifier Ω.

This argument does not generally apply for modalities defined by precomposition, but it does apply to $F(\epsilon_0)$ and $F(\top)$. For instance, $[\![\mathbb{I}_t]\!]$ in $\mathbf{PSh}_{\mathbf{cSet}}(\omega)$ is defined by $[\![\mathbb{I}_t]\!]\, n = [\![\mathbb{I}_s]\!]$. Accordingly, for $\mu = \epsilon_0$ the second isomorphism above is equivalent to requiring an isomorphism between the following presheaves:

$$[\![\Gamma.\{\epsilon_0\}.\mathbb{I}_t]\!]\, n = \begin{cases} [\![\Gamma.\{\mu\}]\!] \times [\![\mathbb{I}_s]\!] & n = 0 \\ \mathbf{0} \end{cases}$$

$$[\![\Gamma.\mathbb{I}_s.\{\epsilon_0\}]\!]\, n = \begin{cases} [\![\Gamma.\{\mu\}]\!] \times [\![\mathbb{I}_s]\!] & n = 0 \\ \mathbf{0} \end{cases}$$

In the above, we have capitalized on the fact that $\mathbf{0} \times X = \mathbf{0}$ in the category of (cubical) sets. Accordingly, we may define (1–3) for all μ in exactly the same manner as Aagaard et al. [1]. That is (1.a), (2), and (3) is realized by the identity and (1.b) is a uniquely defined morphism for every modality μ, regardless of whether or not is defined by right Kan extension and so all necessary coherences are automatically satisfied.

Aside from the above details, no other changes are necessary for our model compared with Aagaard et al. [1]. In particular, no changes to the interpretation of terms or types is necessary. □

Theorem 6.3. *F supports a model of Gatsby.*

Proof. Lemma 6.2 almost suffices, but we must interpret Rule 1. However, since $\langle \top \mid - \rangle$ is interpreted using $\_ \mapsto \mathbf{1}$, we must have $[\![\mathbf{1}.\{\top\}]\!] = \mathbf{0}$. We note that **cSet** is a topos and so $\mathbf{0}$ is a strict initial object. It therefore follows that any object X for which there is a map $X \longrightarrow \mathbf{0}$ must itself be the initial object. The interpretation of Rule 1 is then immediate by the universal property of $\mathbf{0}$. □

Remark 6.4. The same argument scales to $\mathbf{PSh}_{\mathbf{cSet}}(\alpha)$ for an arbitrary limit ordinal α.

Corollary 6.5. *Gatsby is consistent.*

Corollary 6.6. *In the model supported by F, the interpretation of* acc *is true.*

Remark 6.7. Ensuring that Corollary 6.6 holds requires some care. In particular, we take advantage of the flexibility afforded by Aagaard et al. [1] in the construction of the model in $\mathbf{PSh}_{\mathbf{cSet}}(\omega)$. Unlike other other models of guarded cubical type theory [5, 25], we are able to choose the *cofibrations* of our model to be arbitrary monomorphisms. This change is necessary in order to validate acc, whose intepretation is *not* globally true in the model provided by e.g., Kristensen et al. [25].

Remark 6.8. As mentioned in Section 5, we expect for this model to validate the propositional resizing axiom. While we leave developing the details of the argument to future work, we provide a proof sketch to illustrate the evidence of this fact which relies on the Grothendieck universe axiom i.e., that arbitrarily large Grothendieck universes exist. First, note that the two categories used to interpret modes s and t—$\mathbf{cSet}$ and $\mathbf{PSh}_{\mathbf{cSet}}(\omega)$—can both be equipped with model structures for which types are fibrations [14, 17]. In fact, these model structures are *combinatorial* [28, Appendix A.2.6] and so both give rise to presentable ∞-categories and, in light of univalence, Grothendieck ∞-topoi [28, Theorem 6.1.6.8]. Accordingly, the induced ∞-categories presented by these models contain subobject classifiers [28, Proposition 6.1.6.3]. The existence of these subobject classifiers suffices to validate propositional resizing provided the interpretations of $\mathbf{U}_0$ and $\mathbf{U}_1$ are chosen to be large enough universes. We will spell out this argument for $\mathbf{cSet}$, as the other is identical. There must be a fibration $\top_{\mathbf{cSet}} : P^{\bullet}_{\mathbf{cSet}} \longrightarrow P_{\mathbf{cSet}}$ in $\mathbf{cSet}$ which presents this subobject classifier and its tautological map and, choosing $\mathbf{U}_0$ to be interpreted by a sufficiently large universe, we may assume that $\top_{\mathbf{cSet}}$ is $\mathbf{U}_0$-small. Since all families of hProps are (homotopy) pullbacks of $\top_{\mathbf{cSet}}$, this ensures that all families of hProps are equivalent to a family of $\mathbf{U}_0$-small hProps and, in particular, that the map $\mathsf{hProp}_0 \to \mathsf{hProp}_1$ is interpreted by a homotopy equivalence in $\mathbf{cSet}$. In fact, in this situation hProp_i will be equivalent to $P_{\mathbf{cSet}}$ for all i. Note that this argument is highly inefficient in its use of universes—both Cavallo et al. [14] and the argument that $\mathbf{cSet}$ and $\mathbf{PSh}_{\mathbf{cSet}}(\omega)$ present ∞-topoi require arbitrarily large universes. We expect more direct arguments are possible following e.g., Shulman [41, Proposition 11.3].[8] We leave it to future work to elaborate on this argument and, more generally, to explore the ∞-categorical properties validated by these two categories and the corresponding type-theoretical properties.

Beyond merely ensuring consistency, interpreting mode s as the standard model of cubical type theory, ensures a degree of *adequacy* for constructions carried out in Gatsby. In particular, Theorem 6.3 shows that any construction in mode s induces an element in a model already accepted by cubical type theorists. Consequently, there is no need to care about e.g. the topos of trees or modalities when evaluating the content of Theorem 5.1.

More than this, Corollary 6.6 can be generalized to show that any result which holds for so-called homotopy sets in mode t will hold for the corresponding objects in $\mathbf{PSh}(\omega)$. This is in contrast to the models of guarded type theory previously considered [5, 25] where many types behaved in non-standard and unintuitive ways. As this does not impact e.g., Corollary 6.5 or other results in this paper, we defer a proper comparison between these models to future work.

7 Related Work

While many variations on guarded type theory have been proposed [4, 5, 8, 12, 15, 34], these failed to meet at least one of the four goals raised in Thesis 1. Only two prior type theories offer a reasonably

[8] Both arguments, however, rely on classical reasoning, particularly through the theory of presentable ∞-categories. To our knowledge, no constructive model validating propositional resizing is presently known.

complete solution: stratified guarded type theory [20] and clocked cubical type theory [25]. We discussed both in Section 1.3 and we now sharpen our prior comparison.

Stratified guarded type theory. Recall from Section 1.3 that stratified guarded type theory is actually a pair of type theories: one in which Löb computes and one in which it does not. In the type theory where Löb induction computes, Gratzer and Birkedal [20] introduce a notion of guarded canonicity where canonical forms are judged in a special context $\mathbf{0}[\ell^n]$. All terms trivialize when $\mathbf{0}[\ell^n]$ is placed under $\{\ell^n\}$ and so the canonicity result enables one to extract a finite approximation to an infinite canonical form. In Gatsby, $\mathbf{0}[\ell^n]$ can be *defined* as $\mathbf{1}.\{\epsilon_0 \circ e^n\}$. Guarded canonicity becomes a special case of ordinary canonicity.

For example, if we assume acc to prove $M : A$, we may place M under $\langle \epsilon_0 \circ e^n \mid - \rangle$ to discharge acc and obtain an element of $\langle \epsilon_0 \circ e^n \mid A \rangle$. Just as in stratified guarded type theory, we are able to extract information about A from this term but we are only able to descend "beneath n iterations of $\blacktriangleright$". In this way, Gatsby takes the idea of guarded canonicity in stratified guarded type theory and recasts it as a modal discipline. The result is an internalization of guarded canonicity as normal canonicity and, moreover, Gatsby does not rule out normalization in the process.

We have also isolated the universe of accessible types where there is a canonical and optimal choice of fuel and used this to avoid requiring the user to choose a fuel supply each time they wish to calculate a result. Thus, by enriching type theory with modalities and Rule 1, we are able to essentially recover stratified guarded type theory without splitting our theory into two.

Clocked cubical type theory. As described in Section 1.3, clocked cubical type theory ($\mathsf{CloTT}_{\square}$) is an alternative approach to guarded recursion built around indexing $\blacktriangleright$ by a clock. In this way, $\mathsf{CloTT}_{\square}$ allows Löb induction to compute only when the clock indexing the relevant $\blacktriangleright$ modality has been bound. This essentially limits computation to occurring at the top-level and thereby conjecturally preserves canonicity and normalization. A more substantial difference between $\mathsf{CloTT}_{\square}$ and Gatsby is in the approach they take to Löb induction. In $\mathsf{CloTT}_{\square}$—and all other proposed guarded type theories—Löb induction is a primitive while in Gatsby it is derived.

At a high-level, Gatsby provides a richer set of modalities and a simpler semantics, but does not support multi-clock guarded recursion. This means that Gatsby, unlike $\mathsf{CloTT}_{\square}$, can internally express notions such as "constant types" but cannot directly encode a coinductive stream of non-constant types. Despite these differences, both theories conjecturally satisfy the goals of Thesis 1 and so both provide adequate foundations for guarded recursion.

Interestingly, just as our approach to Löb induction necessitates consideration of *accessible types*, the use of clocks in $\mathsf{CloTT}_{\square}$ requires users to frequently restrict to *clock-irrelevant types*. Roughly, these are types which are "clock-null". However, accessible types form a better-behaved class than clock-irrelevant types; accessible types form an open reflective subuniverse [39]. Consequently, we are not only able to show important type operations respect accessibility but also prove that the universe of accessible types is accessible. We are even able to replace a non-accessible type by a universal accessible counterpart. This machinery is not available for clock-irrelevant types; the sort of clocks is not presented as a type but, more fundamentally, it is not a homotopy proposition. Consequently, for instance, the question of whether or not a suitable clock-irrelevant universe of clock-irrelevant types within $\mathsf{CloTT}_{\square}$ [13] remains open.

Other occurrences of accessibility. Finally, we note that variants of the accessibility proposition acc have appeared before in the literature. In Palombi and Sterling [37], for instance, it is used to isolate the universal property of $\mathbf{PSh}(\omega)$ as a model of guarded recursion. That $\exists n.\, \blacktriangleright^n \bot$ holds in $\mathbf{PSh}(\omega)$ is also an important motivation for *transfinite Iris* [43] which uses higher-ordinal models of guarded

recursion precisely to *avoid* having acc = $\top$ hold. Amin Timany has further proposed adding the axiom acc = $\top$ to Iris, as a more intuitive but equivalent formulation of Löb induction [10].

8 Conclusions and Future Work

We have presented Gatsby,[9] a univalent multimodal type theory based on cubical MTT. Proceeding from the observation that Löb induction is an ill-behaved primitive for guarded recursion, Gatsby uses additional modalities to essentially *derive* Löb induction.

Concretely, we isolate a homotopy proposition acc which suffices to imply Löb induction. We then show that the collection of accessible types A—those which are acc-null and therefore support Löb induction—is closed under numerous standard constructions. Gatsby also constrains the modality $\langle \top \mid - \rangle$ to be equivalent to $A \mapsto \mathbf{Unit}$ and this ensures that all constant types are accessible. Using these results, we show that it is possible to encode any program in a standard guarded type theory within Gatsby. We have further exploited Gatsby's rich multimodal structure to improve upon case studies considered already in guarded recursion.

Gatsby constitutes a new point in the space of guarded type theories satisfying Thesis 1 as it captures much of the behavior of the important model of guarded recursion in $\mathbf{PSh}(\omega)$ while still maintaining a well-behaved metatheory.

We summarize several directions for future work below.

8.1 Normalization and Canonicity for Gatsby

At present, we have not proven that Gatsby enjoys either normalization or canonicity. We conjecture that it in fact enjoys both. We offer preliminary evidence in support of this conclusion.

We note that Gatsby is built on top of cubical MTT and we expect to be able to adapt a proof of normalization and canonicity for the latter to apply to the former. At present no such proof for cubical MTT exists, so we begin by discussing prospects for this result.

Cubical MTT is a fusion of two type theories, MTT and cubical type theory, which both enjoy canonicity and normalization [18, 44]. Normalization and canonicity are not modular properties, so this does not necessarily mean that cubical MTT enjoys either. However, given that there are no meaningful interactions between the two theories in cubical MTT, we expect both to hold.

In order to adapt such a proof of normalization and canonicity for cubical MTT to apply to Gatsby, we must show that Rule 1 does not introduce stuck terms and does not disrupt the decidability of normal forms. We expect the techniques used by Sterling and Angiuli [44] to handle the false cofibration should suffice for our situation. In particular, we can show that the crucial lemma of op. cit. stating that it is decidable whether a given context proves the false cofibration can be adapted to Gatsby. That is, it is decidable whether or not there exists a substitution from Γ to $\mathbf{1}.\{\top\}$; it is equivalent to whether one of the following two conditions hold (1) Γ proves the false cofibration or (2) the composite of the modalities in Γ contains $\top$. We give a version of this theorem below which deals with MTT extended by Rule 1 rather than cubical MTT, as the latter involves essentially unrelated details of cubical type theory.

Theorem 8.1. *A substitution $\Gamma \vdash r : \mathbf{1}.\{\top\}$ @ s exists if and only if the composite of all modalities within Γ is $\nu \circ \top$ for some ν.*

Proof Sketch. We do not present the full details of the proof because it requires a more thorough explanation of the substitution calculus of MTT and Gatsby. We begin by noting that there is a trivial model of Gatsby in which every type is interpreted by **Unit**. The category of contexts of this model is a reflective subcategory of the ordinary syntactic category of contexts and substitutions.

[9] The authors defer to the reader on whether or not Gatsby is great.

The reflection sends Γ to a new context $|\Gamma|$ obtained by weakening away all variables in Γ so $|\Gamma|$ is of the form $\mathbf{1}.\{\mu\}$ for some μ.

As $\mathbf{1}.\{\top\}$ lies within this subcategory already, a substitution from Γ to $\mathbf{1}.\{\top\}$ exists just when one there is one from $|\Gamma| = \mathbf{1}.\{\mu\}$ to $\mathbf{1}.\{\top\}$. An inductive argument shows that this occurs just when $\mu \geq \nu \circ \top$ for some ν. However, if $\mu \geq \nu \circ \top$ then $\mu = \nu \circ \top$. □

While the above observations give strong support to our conjecture, normalization and canonicity proofs for any type theory are complex and cubical MTT and Gatsby are both sophisticated type theories. We therefore leave the normalization and canonicity of Gatsby to future work. However, even if one or both of these properties were to fail, we expect that Gatsby could still be a useful pen-and-paper system: one could formulate putative axioms to include in e.g., cubical Agda [49] as a statement in mode s which can then be argued and proven on paper using guarded recursion (c.f., Theorems 4.4 and 5.1).

8.2 Extensions to Gatsby

Aside from extending our knowledge of the metatheory of Gatsby, we hope to study the behavior of other concepts from univalent foundations within this framework. In particular, it remains to isolate which *higher inductive types (HITs)* naturally land within the universe of accessible types. The work on HITs within the context of $\mathsf{CloTT}_{\Box}$ [25] suggests that this may hold for a broad class, though Section 3.3 demonstrates that the situation is subtle. That accessible types form a reflective subuniverse does mean that while this may improve convenience, it is not as vital as the corresponding question for clock-irrelevance.

We have focused on capturing the behavior of guarded recursion within the topos of trees and, in particular, indexing over ω. In the future, we intend to explore whether the idea of isolating accessible types can be adapted to account for indexing over higher ordinals with the goal of modeling $\mathbf{PSh}_{\mathbf{cSet}}(\alpha)$ for at least countable α.

Finally, we intend to explore the behavior of Gatsby further by implementing it. Both MTT and cubical type theories have been implemented in proof assistants and, as discussed in Section 8.1, such implementations should be possible to extend to cubical MTT and Gatsby. Such an implementation would provide a better setting to explore what definitional equalities are possible to achieve in Gatsby, as checking such calculations is subtle and error-prone.

Acknowledgments

We are grateful for useful conversations and feedback from Lars Birkedal, Evan Cavallo, Rasmus Ejlers Møgelberg, and Jonathan Sterling. This work was supported by Villum Fonden through a Villum Investigator grant (25804), the Center for Basic Research in Program Verification (CPV).
